2 Quality criteria, averaging and error estimation

The essential characteristics of our approach to the problem of rating and averaging lattice quantities have been outlined in our first publication \cite{aoki1}. Our aim is to help the reader assess the reliability of a particular lattice result without necessarily studying the original article in depth. This is a delicate issue, since the ratings may make things appear simpler than they are. Nevertheless, it safeguards against the common practice of using lattice results, and drawing physics conclusions from them, without a critical assessment of the quality of the various calculations. We believe that, despite the risks, it is important to provide some compact information about the quality of a calculation. We stress, however, the importance of the accompanying detailed discussion of the results presented in the various sections of the present review.

2.1 Systematic errors and colour code

The major sources of systematic error are common to most lattice calculations. These include, as discussed in detail below, the chiral, continuum, and infinite-volume extrapolations. To each such source of error for which systematic improvement is possible we assign one of three coloured symbols: green star, unfilled green circle (which replaced in Ref. \cite{aoki2} the amber disk used in the original FLAG review \cite{aoki1}) or red square. These correspond to the following ratings:

- ★ the parameter values and ranges used to generate the data sets allow for a satisfactory control of the systematic uncertainties;
- ○ the parameter values and ranges used to generate the data sets allow for a reasonable attempt at estimating systematic uncertainties, which however could be improved;
- ■ the parameter values and ranges used to generate the data sets are unlikely to allow for a reasonable control of systematic uncertainties.

The appearance of a red tag, even in a single source of systematic error of a given lattice result, disqualifies it from inclusion in the global average.

Note that in the first two editions \cite{aoki1, aoki2}, FLAG used the three symbols in order to rate the reliability of the systematic errors attributed to a given result by the paper’s authors. Starting with the previous edition \cite{aoki3} the meaning of the symbols has changed slightly—they now rate the quality of a particular simulation, based on the values and range of the chosen parameters, and its aptness to obtain well-controlled systematic uncertainties. They do not rate the quality of the analysis performed by the authors of the publication. The latter question is deferred to the relevant sections of the present review, which contain detailed discussions of the results contributing (or not) to each FLAG average or estimate.

For most quantities the colour-coding system refers to the following sources of systematic errors: (i) chiral extrapolation; (ii) continuum extrapolation; (iii) finite volume. As we will see below, renormalization is another source of systematic uncertainties in several quantities. This we also classify using the three coloured symbols listed above, but now with a different rationale: they express how reliably these quantities are renormalized, from a field-theoretic point of view (namely, nonperturbatively, or with 2-loop or 1-loop perturbation theory).

Given the sophisticated status that the field has attained, several aspects, besides those rated by the coloured symbols, need to be evaluated before one can conclude whether a particular analysis leads to results that should be included in an average or estimate. Some of these aspects are not so easily expressible in terms of an adjustable parameter such as the lattice spacing, the pion mass or the volume. As a result of such considerations, it
sometimes occurs, albeit rarely, that a given result does not contribute to the FLAG average or estimate, despite not carrying any red tags. This happens, for instance, whenever aspects of the analysis appear to be incomplete (e.g., an incomplete error budget), so that the presence of inadequately controlled systematic effects cannot be excluded. This mostly refers to results with a statistical error only, or results in which the quoted error budget obviously fails to account for an important contribution.

Of course, any colour coding has to be treated with caution; we emphasize that the criteria are subjective and evolving. Sometimes, a single source of systematic error dominates the systematic uncertainty and it is more important to reduce this uncertainty than to aim for green stars for other sources of error. In spite of these caveats, we hope that our attempt to introduce quality measures for lattice simulations will prove to be a useful guide. In addition, we would like to stress that the agreement of lattice results obtained using different actions and procedures provides further validation.

2.1.1 Systematic effects and rating criteria

The precise criteria used in determining the colour coding are unavoidably time-dependent; as lattice calculations become more accurate, the standards against which they are measured become tighter. For this reason FLAG reassesses criteria with each edition and as a result some of the quality criteria (the one on chiral extrapolation for instance) have been tightened up over time [1–3].

In the following, we present the rating criteria used in the current report. While these criteria apply to most quantities without modification there are cases where they need to be amended or additional criteria need to be defined. For instance, when discussing results obtained in the $\epsilon$-regime of chiral perturbation theory in Sec. 5 the finite volume criterion listed below for the $p$-regime is no longer appropriate.\(^1\) Similarly, the discussion of the strong coupling constant in Sec. 9 requires tailored criteria for renormalization, perturbative behaviour, and continuum extrapolation. In such cases, the modified criteria are discussed in the respective sections. Apart from only a few exceptions the following colour code applies in the tables:

- **Chiral extrapolation:**
  - \(\star\) \(M_{\pi,\text{min}} < 200\ \text{MeV}\), with three or more pion masses used in the extrapolation or two values of \(M_\pi\) with one lying within 10 MeV of 135 MeV (the physical neutral pion mass) and the other one below 200 MeV
  - \(200\ \text{MeV} \leq M_{\pi,\text{min}} \leq 400\ \text{MeV}\), with three or more pion masses used in the extrapolation or two values of \(M_\pi\) with \(M_{\pi,\text{min}} < 200\ \text{MeV}\) or a single value of \(M_\pi\), lying within 10 MeV of 135 MeV (the physical neutral pion mass)
  - otherwise

  This criterion has changed with respect to the previous edition [3].

- **Continuum extrapolation:**

\(^1\)We refer to Sec. 5.1 and Appendix A.4 in the Glossary for an explanation of the various regimes of chiral perturbation theory.
at least three lattice spacings and at least two points below 0.1 fm and a range of lattice spacings satisfying $[a_{\text{max}}/a_{\text{min}}]^2 \geq 2$

- at least two lattice spacings and at least one point below 0.1 fm and a range of lattice spacings satisfying $[a_{\text{max}}/a_{\text{min}}]^2 \geq 1.4$

- otherwise

It is assumed that the lattice action is $O(a)$-improved (i.e., the discretization errors vanish quadratically with the lattice spacing); otherwise this will be explicitly mentioned. For unimproved actions an additional lattice spacing is required. This condition is unchanged from Ref. [3].

- Finite-volume effects:

The finite-volume colour code used for a result is chosen to be the worse of the QCD and the QED codes, as described below. If only QCD is used the QED colour code is ignored.

- For QCD:

  - $\star$ $[M_{\pi,\text{min}}/M_{\pi,\text{fid}}]^2 \exp\{4 - M_{\pi,\text{min}}[L(M_{\pi,\text{min}})]_{\text{max}}\} < 1$, or at least three volumes

  - $\circ$ $[M_{\pi,\text{min}}/M_{\pi,\text{fid}}]^2 \exp\{3 - M_{\pi,\text{min}}[L(M_{\pi,\text{min}})]_{\text{max}}\} < 1$, or at least two volumes

  - ■ otherwise

where we have introduced $[L(M_{\pi,\text{min}})]_{\text{max}}$, which is the maximum box size used in the simulations performed at the smallest pion mass $M_{\pi,\text{min}}$, as well as a fiducial pion mass $M_{\pi,\text{fid}}$, which we set to 200 MeV (the cutoff value for a green star in the chiral extrapolation). It is assumed here that calculations are in the $p$-regime of chiral perturbation theory, and that all volumes used exceed 2 fm. This condition has been improved between the second [2] and the third [3] edition of the FLAG review but remains unchanged since. The rationale for this condition is as follows. Finite volume effects contain the universal factor $\exp\{-L M_{\pi}\}$, and if this were the only contribution a criterion based on the values of $M_{\pi,\text{min}}L$ would be appropriate. This is what we used in Ref. [2] (with $M_{\pi,\text{min}}L > 4$ for $\star$ and $M_{\pi,\text{min}}L > 3$ for $\circ$). However, as pion masses decrease, one must also account for the weakening of the pion couplings. In particular, 1-loop chiral perturbation theory [4] reveals a behaviour proportional to $M_{\pi}^2 \exp\{-L M_{\pi}\}$. Our new condition includes this weakening of the coupling, and ensures, for example, that simulations with $M_{\pi,\text{min}} = 135$ MeV and $L M_{\pi,\text{min}} = 3.2$ are rated equivalently to those with $M_{\pi,\text{min}} = 200$ MeV and $L M_{\pi,\text{min}} = 4$.

- For QED (where applicable):

  - $\star$ $1/([M_{\pi,\text{min}}L(M_{\pi,\text{min}})]_{\text{max}})^{n_{\text{min}}} < 0.02$, or at least four volumes

  - $\circ$ $1/([M_{\pi,\text{min}}L(M_{\pi,\text{min}})]_{\text{max}})^{n_{\text{min}}} < 0.04$, or at least three volumes

  - ■ otherwise

Because of the infrared-singular structure of QED, electromagnetic finite-volume effects decay only like a power of the inverse spatial extent. In several cases like mass splittings [5, 6] or leptonic decays [7], the leading corrections are known to be universal, i.e., independent of the structure of the involved hadrons. In such cases, the leading universal effects can be directly subtracted exactly from the lattice data. We denote $n_{\text{min}}$ the smallest power of $1/L$ at which such a subtraction cannot be done. In the widely used finite-volume formulation QED$_L$, one always has $n_{\text{min}} \leq 3$ due to the nonlocality
of the theory [8]. While the QCD criteria have not changed with respect to Ref. [3] the QED criteria are new. They are used here only in Sec. 3.

- Isospin breaking effects (where applicable):
  - ★ all leading isospin breaking effects are included in the lattice calculation
  - ○ isospin breaking effects are included using the electro-quenched approximation
  - ■ otherwise

This criterion is used for quantities which are breaking isospin symmetry or which can be determined at the sub-percent accuracy where isospin breaking effects, if not included, are expected to be the dominant source of uncertainty. In the current edition, this criterion is only used for the up and down quark masses, and related quantities ($\epsilon$, $Q^2$ and $R^2$). The criteria for isospin breaking effects feature for the first time in the FLAG review.

- Renormalization (where applicable):
  - ★ nonperturbative
  - ○ 1-loop perturbation theory or higher with a reasonable estimate of truncation errors
  - ■ otherwise

In Ref. [1], we assigned a red square to all results which were renormalized at 1-loop in perturbation theory. In Ref. [2], we decided that this was too restrictive, since the error arising from renormalization constants, calculated in perturbation theory at 1-loop, is often estimated conservatively and reliably. We did not change these criteria since.

- Renormalization Group (RG) running (where applicable):
  For scale-dependent quantities, such as quark masses or $B_K$, it is essential that contact with continuum perturbation theory can be established. Various different methods are used for this purpose (cf. Appendix A.3): Regularization-independent Momentum Subtraction (RI/MOM), the Schrödinger functional, and direct comparison with (resummed) perturbation theory. Irrespective of the particular method used, the uncertainty associated with the choice of intermediate renormalization scales in the construction of physical observables must be brought under control. This is best achieved by performing comparisons between nonperturbative and perturbative running over a reasonably broad range of scales. These comparisons were initially only made in the Schrödinger functional approach, but are now also being performed in RI/MOM schemes. We mark the data for which information about nonperturbative running checks is available and give some details, but do not attempt to translate this into a colour code.

The pion mass plays an important role in the criteria relevant for chiral extrapolation and finite volume. For some of the regularizations used, however, it is not a trivial matter to identify this mass. In the case of twisted-mass fermions, discretization effects give rise to a mass difference between charged and neutral pions even when the up- and down-quark masses are equal: the charged pion is found to be the heavier of the two for twisted-mass Wilson fermions (cf. Ref. [9]). In early works, typically referring to $N_f = 2$ simulations (e.g., Refs. [9] and [10]), chiral extrapolations are based on chiral perturbation theory formulae which do not take these regularization effects into account. After the importance of accounting for isospin breaking when doing chiral fits was shown in Ref. [11], later works, typically referring to
$N_f = 2+1+1$ simulations, have taken these effects into account \cite{12}. We use $M_{\pi^\pm}$ for $M_{\pi,\text{min}}$ in the chiral-extrapolation rating criterion. On the other hand, we identify $M_{\pi,\text{min}}$ with the root mean square (RMS) of $M_{\pi^+}$, $M_{\pi^-}$ and $M_{\pi^0}$ in the finite-volume rating criterion.\footnote{This is a change from FLAG 13, where we used the charged pion mass when evaluating both chiral-extrapolation and finite-volume effects.}

In the case of staggered fermions, discretization effects give rise to several light states with the quantum numbers of the pion.\footnote{We refer the interested reader to a number of good reviews on the subject \cite{13–17}.} The mass splitting among these “taste” partners represents a discretization effect of $O(a^2)$, which can be significant at large lattice spacings but shrinks as the spacing is reduced. In the discussion of the results obtained with staggered quarks given in the following sections, we assume that these artifacts are under control. We conservatively identify $M_{\pi,\text{min}}$ with the root mean square (RMS) average of the masses of all the taste partners, both for chiral-extrapolation and finite-volume criteria.\footnote{In FLAG 13, the RMS value was used in the chiral-extrapolation criteria throughout the paper. For the finite-volume rating, however, $M_{\pi,\text{min}}$ was identified with the RMS value only in Secs. 4 and 6, while in Secs. 3, 5, 7 and 8 it was identified with the mass of the lightest pseudoscalar state.}

The strong coupling $\alpha_s$ is computed in lattice QCD with methods differing substantially from those used in the calculations of the other quantities discussed in this review. Therefore, we have established separate criteria for $\alpha_s$ results, which will be discussed in Sec. 9.2.1.

In the new section on nuclear matrix elements, Sec. 10, an additional criterion has been introduced. This concerns the level of control over contamination from excited states, which is a more challenging issue for nucleons than for mesons. In addition, the chiral-extrapolation criterion in this section is somewhat stricter than that given above.

### 2.1.2 Heavy-quark actions

For the $b$ quark, the discretization of the heavy-quark action follows a very different approach from that used for light flavours. There are several different methods for treating heavy quarks on the lattice, each with its own issues and considerations. All of these methods use Effective Field Theory (EFT) at some point in the computation, either via direct simulation of the EFT, or by using EFT as a tool to estimate the size of cutoff errors, or by using EFT to extrapolate from the simulated lattice quark masses up to the physical $b$-quark mass. Because of the use of an EFT, truncation errors must be considered together with discretization errors.

The charm quark lies at an intermediate point between the heavy and light quarks. In our earlier reviews, the calculations involving charm quarks often treated it using one of the approaches adopted for the $b$ quark. Since the last report \cite{3}, however, we found more recent calculations to simulate the charm quark using light-quark actions. This has become possible thanks to the increasing availability of dynamical gauge field ensembles with fine lattice spacings. But clearly, when charm quarks are treated relativistically, discretization errors are more severe than those of the corresponding light-quark quantities.

In order to address these complications, we add a new heavy-quark treatment category to the rating system. The purpose of this criterion is to provide a guideline for the level of action and operator improvement needed in each approach to make reliable calculations possible, in principle.

A description of the different approaches to treating heavy quarks on the lattice is given in Appendix A.1.3, including a discussion of the associated discretization, truncation, and matching errors. For truncation errors we use HQET power counting throughout, since this
review is focused on heavy-quark quantities involving $B$ and $D$ mesons rather than bottomo-
nium or charmonium quantities. Here we describe the criteria for how each approach must be
implemented in order to receive an acceptable (√) rating for both the heavy-quark actions
and the weak operators. Heavy-quark implementations without the level of improvement
described below are rated not acceptable (■). The matching is evaluated together with
renormalization, using the renormalization criteria described in Sec. 2.1.1. We emphasize
that the heavy-quark implementations rated as acceptable and described below have been
validated in a variety of ways, such as via phenomenological agreement with experimental
measurements, consistency between independent lattice calculations, and numerical studies
of truncation errors. These tests are summarized in Sec. 8.

Relativistic heavy-quark actions:
√ at least tree-level $O(a)$ improved action and weak operators
This is similar to the requirements for light-quark actions. All current implementations of
relativistic heavy-quark actions satisfy this criterion.

$NRQCD$:
√ tree-level matched through $O(1/m_h)$ and improved through $O(a^2)$
The current implementations of NRQCD satisfy this criterion, and also include tree-level cor-
rections of $O(1/m_h^2)$ in the action.

$HQET$:
√ tree-level matched through $O(1/m_h)$ with discretization errors starting at $O(a^2)$
The current implementation of HQET by the ALPHA collaboration satisfies this criterion,
since both action and weak operators are matched nonperturbatively through $O(1/m_h)$. Cal-
culations that exclusively use a static-limit action do not satisfy this criterion, since the
static-limit action, by definition, does not include $1/m_h$ terms. We therefore include static
computations in our final estimates only if truncation errors (in $1/m_h$) are discussed and
included in the systematic uncertainties.

Light-quark actions for heavy quarks:
√ discretization errors starting at $O(a^2)$ or higher
This applies to calculations that use the $tm$Wilson action, a nonperturbatively improved Wil-
son action, domain wall fermions or the HISQ action for charm-quark quantities. It also
applies to calculations that use these light quark actions in the charm region and above to-
gether with either the static limit or with an HQET-inspired extrapolation to obtain results
at the physical $b$-quark mass. In these cases, the continuum-extrapolation criteria described
earlier must be applied to the entire range of heavy-quark masses used in the calculation.

2.1.3 Conventions for the figures
For a coherent assessment of the present situation, the quality of the data plays a key role, but
the colour coding cannot be carried over to the figures. On the other hand, simply showing
all data on equal footing might give the misleading impression that the overall consistency of
the information available on the lattice is questionable. Therefore, in the figures we indicate
the quality of the data in a rudimentary way, using the following symbols:
■ corresponds to results included in the average or estimate (i.e., results that contribute
to the black square below);
□ corresponds to results that are not included in the average but pass all quality criteria;
□ corresponds to all other results;
corresponds to FLAG averages or estimates; they are also highlighted by a gray vertical band. The reason for not including a given result in the average is not always the same: the result may fail one of the quality criteria; the paper may be unpublished; it may be superseded by newer results; or it may not offer a complete error budget.

Symbols other than squares are used to distinguish results with specific properties and are always explained in the caption.5

Often, nonlattice data are also shown in the figures for comparison. For these we use the following symbols:

- corresponds to nonlattice results;
- ▲ corresponds to Particle Data Group (PDG) results.

2.2 Averages and estimates

FLAG results of a given quantity are denoted either as averages or as estimates. Here we clarify this distinction. To start with, both averages and estimates are based on results without any red tags in their colour coding. For many observables there are enough independent lattice calculations of good quality, with all sources of error (not merely those related to the colour-coded criteria), as analyzed in the original papers, appearing to be under control. In such cases, it makes sense to average these results and propose such an average as the best current lattice number. The averaging procedure applied to this data and the way the error is obtained is explained in detail in Sec. 2.3. In those cases where only a sole result passes our rating criteria (colour coding), we refer to it as our FLAG average, provided it also displays adequate control of all other sources of systematic uncertainty.

On the other hand, there are some cases in which this procedure leads to a result that, in our opinion, does not cover all uncertainties. Systematic errors are by their nature often subjective and difficult to estimate, and may thus end up being underestimated in one or more results that receive green symbols for all explicitly tabulated criteria. Adopting a conservative policy, in these cases we opt for an estimate (or a range), which we consider as a fair assessment of the knowledge acquired on the lattice at present. This estimate is not obtained with a prescribed mathematical procedure, but reflects what we consider the best possible analysis of the available information. The hope is that this will encourage more detailed investigations by the lattice community.

There are two other important criteria that also play a role in this respect, but that cannot be colour coded, because a systematic improvement is not possible. These are: i) the publication status, and ii) the number of sea-quark flavours \( N_f \). As far as the former criterion is concerned, we adopt the following policy: we average only results that have been published in peer-reviewed journals, i.e., they have been endorsed by referee(s). The only exception to this rule consists in straightforward updates of previously published results, typically presented in conference proceedings. Such updates, which supersede the corresponding results in the published papers, are included in the averages. Note that updates of earlier results rely, at least partially, on the same gauge-field-configuration ensembles. For this reason, we do not

5For example, for quark-mass results we distinguish between perturbative and nonperturbative renormalization, for low-energy constants we distinguish between the \( p \)- and \( \epsilon \)-regimes, and for heavy-flavour results we distinguish between those from leptonic and semi-leptonic decays.
average updates with earlier results. Nevertheless, all results are listed in the tables, and their publication status is identified by the following symbols:

- **Publication status:**
  - A published or plain update of published results
  - P preprint
  - C conference contribution

In the present edition, the publication status on the **30th of September 2018** is relevant. If the paper appeared in print after that date, this is accounted for in the bibliography, but does not affect the averages.7

As noted above, in this review we present results from simulations with $N_f = 2$, $N_f = 2+1$ and $N_f = 2 + 1 + 1$ (except for $r_0\Lambda_{\overline{MS}}$ where we also give the $N_f = 0$ result). We are not aware of an *a priori* way to quantitatively estimate the difference between results produced in simulations with a different number of dynamical quarks. We therefore average results at fixed $N_f$ separately; averages of calculations with different $N_f$ are not provided.

To date, no significant differences between results with different values of $N_f$ have been observed in the quantities listed in Tabs. 1, 2, and 3. In the future, as the accuracy and the control over systematic effects in lattice calculations increases, it will hopefully be possible to see a difference between results from simulations with $N_f = 2$ and $N_f = 2 + 1$, and thus determine the size of the Zweig-rule violations related to strange-quark loops. This is a very interesting issue *per se*, and one which can be quantitatively addressed only with lattice calculations.

The question of differences between results with $N_f = 2 + 1$ and $N_f = 2 + 1 + 1$ is more subtle. The dominant effect of including the charm sea quark is to shift the lattice scale, an effect that is accounted for by fixing this scale nonperturbatively using physical quantities. For most of the quantities discussed in this review, it is expected that residual effects are small in the continuum limit, suppressed by $\alpha_s(m_c)$ and powers of $\Lambda^2/m_c^2$. Here $\Lambda$ is a hadronic scale that can only be roughly estimated and depends on the process under consideration. Note that the $\Lambda^2/m_c^2$ effects have been addressed in Refs. [18, 19]. Assuming that such effects are small, it might be reasonable to average the results from $N_f = 2 + 1$ and $N_f = 2 + 1 + 1$ simulations.

### 2.3 Averaging procedure and error analysis

In the present report, we repeatedly average results obtained by different collaborations, and estimate the error on the resulting averages. Here we provide details on how averages are obtained.

#### 2.3.1 Averaging — generic case

We follow the procedure of the previous two editions [2, 3], which we describe here in full detail.

One of the problems arising when forming averages is that not all of the data sets are independent. In particular, the same gauge-field configurations, produced with a given fermion

---

6Whenever figures turn out to be overcrowded, older, superseded results are omitted. However, all the most recent results from each collaboration are displayed.

7As noted above in footnote 1, three exceptions to this deadline were made.
discretization, are often used by different research teams with different valence-quark lattice actions, obtaining results that are not really independent. Our averaging procedure takes such correlations into account.

Consider a given measurable quantity $Q$, measured by $M$ distinct, not necessarily uncorrelated, numerical experiments (simulations). The result of each of these measurements is expressed as

$$Q_i = x_i \pm \sigma_i^{(1)} \pm \sigma_i^{(2)} \pm \cdots \pm \sigma_i^{(E)},$$

where $x_i$ is the value obtained by the $i$th experiment ($i = 1, \cdots, M$) and $\sigma_i^{(k)}$ (for $k = 1, \cdots, E$) are the various errors. Typically $\sigma_i^{(1)}$ stands for the statistical error and $\sigma_i^{(\alpha)}$ ($\alpha \geq 2$) are the different systematic errors from various sources. For each individual result, we estimate the total error $\sigma_i$ by adding statistical and systematic errors in quadrature:

$$\sigma_i \equiv \sqrt{E \sum_{\alpha=1}^{\alpha=E} \sigma_i^{(\alpha)}^2}.$$  

With the weight factor of each total error estimated in standard fashion,

$$\omega_i = \frac{\sigma_i^{-2}}{\sum_{i=1}^{M} \sigma_i^{-2}},$$

the central value of the average over all simulations is given by

$$x_{av} = \frac{1}{M} \sum_{i=1}^{M} x_i \omega_i.$$  

The above central value corresponds to a $\chi^2_{min}$ weighted average, evaluated by adding statistical and systematic errors in quadrature. If the fit is not of good quality ($\chi^2_{min}/\text{dof} > 1$), the statistical and systematic error bars are stretched by a factor $S = \sqrt{\chi^2/\text{dof}}$.

Next, we examine error budgets for individual calculations and look for potentially correlated uncertainties. Specific problems encountered in connection with correlations between different data sets are described in the text that accompanies the averaging. If there is reason to believe that a source of error is correlated between two calculations, a 100% correlation is assumed. The correlation matrix $C_{ij}$ for the set of correlated lattice results is estimated by a prescription due to Schmelling [20]. This consists in defining

$$\sigma_{ij} = \sqrt{\sum_{\alpha} \sigma_i^{(\alpha)} \sigma_j^{(\alpha)}},$$

with $\sum'_{\alpha}$ running only over those errors of $x_i$ that are correlated with the corresponding errors of the measurement $x_j$. This expresses the part of the uncertainty in $x_i$ that is correlated with the uncertainty in $x_j$. If no such correlations are known to exist, then we take $\sigma_{ij} = 0$. The diagonal and off-diagonal elements of the correlation matrix are then taken to be

$$C_{ii} = \sigma_i^2 \quad (i = 1, \cdots, M),$$

$$C_{ij} = \sigma_{ij} \sigma_{ji} \quad (i \neq j).$$

Finally, the error of the average is estimated by

\[ \sigma_{av}^2 = \sum_{i=1}^{M} \sum_{j=1}^{M} \omega_i \omega_j C_{ij}, \]  

and the FLAG average is

\[ Q_{av} = x_{av} \pm \sigma_{av}. \]  

### 2.3.2 Nested averaging

We have encountered one case where the correlations between results are more involved, and a nested averaging scheme is required. This concerns the $B$-meson bag parameters discussed in Sec. 8.2. In the following, we describe the details of the nested averaging scheme. This is an updated version of the section added in the web update of the FLAG 16 report.

The issue arises for a quantity $Q$ that is given by a ratio, $Q = Y/Z$. In most simulations, both $Y$ and $Z$ are calculated, and the error in $Q$ can be obtained in each simulation in the standard way. However, in other simulations only $Y$ is calculated, with $Z$ taken from a global average of some type. The issue to be addressed is that this average value $Z$ has errors that are correlated with those in $Q$.

In the example that arises in Sec. 8.2, $Q = B_B$, $Y = B_B f_B^2$, and $Z = f_B^2$. In one of the simulations that contribute to the average, $Z$ is replaced by $Z_0$, the PDG average for $f_B^2$ [21] (obtained with an averaging procedure similar to that used by FLAG). This simulation is labeled with $i = 1$, so that

\[ Q_1 = \frac{Y_1}{Z}. \]  

The other simulations have results labeled $Q_j$, with $j \geq 2$. In this set up, the issue is that $Z$ is correlated with the $Q_j$, $j \geq 2$.

We begin by decomposing the error in $Q_1$ in the same schematic form as above,

\[ Q_1 = x_1 \pm \frac{\sigma_{Y_1}^{(1)}}{Z} \pm \frac{\sigma_{Y_1}^{(2)}}{Z} \pm \cdots \pm \frac{\sigma_{Y_1}^{(E)}}{Z} \pm \frac{Y_1 \sigma_Z}{Z^2}. \]  

Here the last term represents the error propagating from that in $Z$, while the others arise from errors in $Y_1$. For the remaining $Q_j$ ($j \geq 2$) the decomposition is as in Eq. (1). The total error of $Q_1$ then reads

\[ \sigma_1^2 = \left( \frac{\sigma_{Y_1}^{(1)}}{Z} \right)^2 + \left( \frac{\sigma_{Y_1}^{(2)}}{Z} \right)^2 + \cdots + \left( \frac{\sigma_{Y_1}^{(E)}}{Z} \right)^2 + \left( \frac{Y_1 \sigma_Z}{Z^2} \right)^2 \sigma_Z^2, \]  

while that for the $Q_j$ ($j \geq 2$) is

\[ \sigma_j^2 = \left( \sigma_j^{(1)} \right)^2 + \left( \sigma_j^{(2)} \right)^2 + \cdots + \left( \sigma_j^{(E)} \right)^2. \]  

\[ ^8\text{There is also a small correlation between } Y_1 \text{ and } Z, \text{ but we follow the original Ref. [22] and do not take this into account. Thus, the error in } Q_1 \text{ is obtained by simple error propagation from those in } Y_1 \text{ and } Z. \text{ Ignoring this correlation is conservative, because, as in the calculation of } B_K, \text{ the correlations between } B_B f_B^2 \text{ and } f_B^2 \text{ tend to lead to a cancelation of errors. By ignoring this effect we are making a small overestimate of the error in } Q_1. \]
Correlations between $Q_j$ and $Q_k$ ($j, k \geq 2$) are taken care of by Schmelling’s prescription, as explained above. What is new here is how the correlations between $Q_1$ and $Q_j$ ($j \geq 2$) are taken into account.

To proceed, we recall from Eq. (7) that $\sigma_Z$ is given by

$$\sigma^2_Z = \sum_{\alpha'j'=1}^{M'} \omega[Z]_{\alpha'j'} \omega[Z]_{j'j} C[Z]_{\alpha'j'}. \quad (13)$$

Here the indices $\alpha'$ and $j'$ run over the $M'$ simulations that contribute to $Z$, which, in general, are different from those contributing to the results for $Q$. The weights $\omega[Z]$ and correlation matrix $C[Z]$ are given an explicit argument $Z$ to emphasize that they refer to the calculation of this quantity and not to that of $Q$. $C[Z]$ is calculated using the Schmelling prescription [Eqs. (5)–(7)] in terms of the errors, $\sigma[Z]_{\alpha'}$, taking into account the correlations between the different calculations of $Z$.

We now generalize Schmelling’s prescription for $\sigma_{i,j}$, Eq. (5), to that for $\sigma_{1,k}$ ($k \geq 2$), i.e., the part of the error in $Q_1$ that is correlated with $Q_k$. We take

$$\sigma_{1,k} = \sqrt{\frac{1}{Z} \sum_{(\alpha)+k} \left[\sigma_{Y_1}^{(\alpha)}\right]^2 + \frac{Y^2}{Z} \sum_{\alpha'}^{M'} \omega[Z]_{\alpha'j'} \omega[Z]_{j'j} C[Z]_{\alpha'j'\alpha+k}}. \quad (14)$$

The first term under the square root sums those sources of error in $Y_1$ that are correlated with $Q_k$. Here we are using a more explicit notation from that in Eq. (5), with $(\alpha) \leftrightarrow k$ indicating that the sum is restricted to the values of $\alpha$ for which the error $\sigma_{Y1}^{(\alpha)}$ is correlated with $Q_k$. The second term accounts for the correlations within $Z$ with $Q_k$, and is the nested part of the present scheme. The new matrix $C[Z]_{i'j'\alpha+k}$ is a restriction of the full correlation matrix $C[Z]$, and is defined as follows. Its diagonal elements are given by

$$C[Z]_{i'\alpha+k} = (\sigma[Z]_{i'\alpha+k})^2 \quad (i' = 1, \cdots, M'), \quad (15)$$

$$\sigma[Z]_{\alpha+k} = \sum_{(\alpha)+k} \left[\sigma[Z]^{(\alpha)}_{\alpha'}\right]^2, \quad (16)$$

where the summation $\sum_{(\alpha)+k}$ over $(\alpha)$ is restricted to those $\sigma[Z]^{(\alpha)}_{\alpha'}$ that are correlated with $Q_k$. The off-diagonal elements are

$$C[Z]_{i'j'\alpha+k} = \sigma[Z]_{i'\alpha+k} \sigma[Z]_{j'\alpha+k} \quad (i' \neq j'), \quad (17)$$

$$\sigma[Z]_{i'j'\alpha+k} = \sqrt{\sum_{(\alpha)+j'k} \left[\sigma[Z]^{(\alpha)}_{\alpha'}\right]^2}, \quad (18)$$

where the summation $\sum_{(\alpha)+j'k}$ over $(\alpha)$ is restricted to $\sigma[Z]^{(\alpha)}_{\alpha'}$ that are correlated with both $Z_{j'}$ and $Q_k$.

The last quantity that we need to define is $\sigma_{k;1}$.

$$\sigma_{k;1} = \sqrt{\sum_{(\alpha)+1} \left[\sigma_{k}^{(\alpha)}\right]^2}, \quad (19)$$
where the summation $\sum_{(a)\rightarrow k}$ is restricted to those $\sigma^{(a)}_k$ that are correlated with one of the terms in Eq. (11).

In summary, we construct the correlation matrix $C_{ij}$ using Eq. (6), as in the generic case, except the expressions for $\sigma_{1,k}$ and $\sigma_{k,1}$ are now given by Eqs. (14) and (19), respectively. All other $\sigma_{i,j}$ are given by the original Schmelling prescription, Eq. (5). In this way we extend the philosophy of Schmelling’s approach while accounting for the more involved correlations.
