3 Quark masses

Authors: T. Blum, A. Portelli, A. Ramos

Quark masses are fundamental parameters of the Standard Model. An accurate determination of these parameters is important for both phenomenological and theoretical applications. The bottom- and charm-quark masses, for instance, are important sources of parametric uncertainties in several Higgs decay modes. The up-, down- and strange-quark masses govern the amount of explicit chiral symmetry breaking in QCD. From a theoretical point of view, the values of quark masses provide information about the flavour structure of physics beyond the Standard Model. The Review of Particle Physics of the Particle Data Group contains a review of quark masses [1], which covers light as well as heavy flavours. Here we also consider light- and heavy-quark masses, but focus on lattice results and discuss them in more detail. We do not discuss the top quark, however, because it decays weakly before it can hadronize, and the nonperturbative QCD dynamics described by present day lattice simulations is not relevant. The lattice determination of light- (up, down, strange), charm- and bottom-quark masses is considered below in Secs. 3.1, 3.2, and 3.3, respectively.

Quark masses cannot be measured directly in experiment because quarks cannot be isolated, as they are confined inside hadrons. From a theoretical point of view, in QCD with $N_f$ flavours, a precise definition of quark masses requires one to choose a particular renormalization scheme. This renormalization procedure introduces a renormalization scale $\mu$, and quark masses depend on this renormalization scale according to the Renormalization Group (RG) equations. In mass-independent renormalization schemes the RG equations reads

$$\mu \frac{d \bar{m}_i(\mu)}{d \mu} = \bar{m}_i(\mu) \tau(\bar{g}), \quad (20)$$

where the function $\tau(\bar{g})$ is the anomalous dimension, which depends only on the value of the strong coupling $\alpha_s = \bar{g}^2/(4\pi)$. Note that in QCD $\tau(\bar{g})$ is the same for all quark flavours. The anomalous dimension is scheme dependent, but its perturbative expansion

$$\tau(\bar{g}) \approx -\bar{g}^2 (d_0 + d_1 \bar{g}^2 + \ldots) \quad (21)$$

has a leading coefficient $d_0 = 8/(4\pi)^2$, which is scheme independent.\footnote{We follow the conventions of Gasser and Leutwyler [2].} Equation (20), being a first order differential equation, can be solved exactly by using Eq. (21) as boundary condition. The formal solution of the RG equation reads

$$M_i = \bar{m}_i(\mu)[2b_0 \bar{g}^2(\mu)]^{-d_0/(2b_0)} \exp \left\{ - \int_{0}^{\bar{g}(\mu)} dx \left[ \frac{\tau(x)}{\beta(x)} - \frac{d_0}{b_0 x} \right] \right\}, \quad (22)$$

where $b_0 = (11 - 2N_f/3)/(4\pi)^2$ is the universal leading perturbative coefficient in the expansion of the $\beta$-function $\beta(\bar{g})$. The renormalization group invariant (RGI) quark masses $M_i$ are formally integration constants of the RG Eq. (20). They are scale independent, and due to the universality of the coefficient $d_0$, they are also scheme independent. Moreover, they are nonperturbatively defined by Eq. (22). They only depend on the number of flavours $N_f$, making them a natural candidate to quote quark masses and compare determinations from different lattice collaborations. Nevertheless, it is customary in the phenomenology community to use...
the $\overline{\text{MS}}$ scheme at a scale $\mu = 2$ GeV to compare different results for light-quark masses, and use a scale equal to its own mass for the charm and bottom quarks. In this review, we will quote the final averages of both quantities.

Results for quark masses are always quoted in the four-flavour theory. $N_f = 2 + 1$ results have to be converted to the four flavour theory. Fortunately, the charm quark is heavy $(\Lambda_{\text{QCD}}/m_c)^2 < 1$, and this conversion can be performed in perturbation theory with negligible ($\sim 0.2\%$) perturbative uncertainties. Nonperturbative corrections in this matching are more difficult to estimate. Since these effects are suppressed by a factor of $1/N_c$, and a factor of the strong coupling at the scale of the charm mass, naive power counting arguments would suggest that the effects are $\sim 1\%$. In practice, numerical nonperturbative studies [3, 4] have found this power counting argument to be an overestimate by one order of magnitude in the determination of simple hadronic quantities or the $\Lambda$-parameter. Moreover, lattice determinations do not show any significant deviation between the $N_f = 2 + 1$ and $N_f = 2 + 1 + 1$ simulations. For example, the difference in the final averages for the mass of the strange quark $m_s$ between $N_f = 2 + 1$ and $N_f = 2 + 1 + 1$ determinations is about a 0.8%, and negligible from a statistical point of view.

We quote all final averages at 2 GeV in the $\overline{\text{MS}}$ scheme and also the RGI values (in the four flavour theory). We use the exact RG Eq. (22). Note that to use this equation we need the value of the strong coupling in the $\overline{\text{MS}}$ scheme at a scale $\mu = 2$ GeV. All our results are obtained from the RG equation in the $\overline{\text{MS}}$ scheme and the 5-loop beta function together with the value of the $\Lambda$-parameter in the four-flavour theory $\Lambda_{\overline{\text{MS}}}^{(4)} = 294(12)$ MeV obtained in this review (see Sec. 9). In the uncertainties of the RGI masses we separate the contributions from the determination of the quark masses and the propagation of the uncertainty of $\Lambda_{\overline{\text{MS}}}^{(4)}$. These are identified with the subscripts $\text{m}$ and $\Lambda$, respectively.

Conceptually, all lattice determinations of quark masses contain three basic ingredients:

1. Tuning the lattice bare-quark masses to match the experimental values of some quantities. Pseudo-scalar meson masses provide the most common choice, since they have a strong dependence on the values of quark masses. In pure QCD with $N_f$ quark flavours these values are not known, since the electromagnetic interactions affect the experimental values of meson masses. Therefore, pure QCD determinations use model/lattice information to determine the location of the physical point. This is discussed at length in Sec. 3.1.1.

2. Renormalization of the bare-quark masses. Bare-quark masses determined with the above-mentioned criteria have to be renormalized. Many of the latest determinations use some nonperturbatively defined scheme. One can also use perturbation theory to connect directly the values of the bare-quark masses to the values in the $\overline{\text{MS}}$ scheme at 2 GeV. Experience shows that 1-loop calculations are unreliable for the renormalization of quark masses: usually at least two loops are required to have trustworthy results.

3. If quark masses have been nonperturbatively renormalized, for example, to some MOM/SF scheme, the values in this scheme must be converted to the phenomenologically useful values in the $\overline{\text{MS}}$ scheme (or to the scheme/scale independent RGI masses). Either option requires the use of perturbation theory. The larger the energy scale of this matching with perturbation theory, the better, and many recent computations in MOM schemes do a nonperturbative running up to $3 - 4$ GeV. Computations in the SF scheme allow
us to perform this running nonperturbatively over large energy scales and match with
perturbation theory directly at the electro-weak scale $\sim 100$ GeV.

Note that quark masses are different from other quantities determined on the lattice since
perturbation theory is unavoidable when matching to schemes in the continuum.

We mention that lattice-QCD calculations of the $b$-quark mass have an additional compi-
lcation which is not present in the case of the charm and light quarks. At the lattice spacings
currently used in numerical simulations the direct treatment of the $b$ quark with the fermionic
actions commonly used for light quarks is very challenging. Only one determination of the
$b$-quark mass uses this approach, reaching the physical $b$-quark mass region at two lattice
spacings with $am \sim 0.9$ and 0.64, respectively (see Sec. 3.3). There are a few widely used
approaches to treat the $b$ quark on the lattice, which have been already discussed in the FLAG
13 review (see Sec. 8 of Ref. [5]). Those relevant for the determination of the $b$-quark mass
will be briefly described in Sec. 3.3.

3.1 Masses of the light quarks

Light-quark masses are particularly difficult to determine because they are very small (for the
up and down quarks) or small (for the strange quark) compared to typical hadronic scales.
Thus, their impact on typical hadronic observables is minute, and it is difficult to isolate their
contribution accurately.

Fortunately, the spontaneous breaking of $SU(3)_L \times SU(3)_R$ chiral symmetry provides
observables which are particularly sensitive to the light-quark masses: the masses of the
resulting Nambu-Goldstone bosons (NGB), i.e., pions, kaons, and eta. Indeed, the Gell-Mann-
Oakes-Renner relation [6] predicts that the squared mass of a NGB is directly proportional to
the sum of the masses of the quark and antiquark which compose it, up to higher-order mass
corrections. Moreover, because these NGBs are light, and are composed of only two valence
particles, their masses have a particularly clean statistical signal in lattice-QCD calculations.
In addition, the experimental uncertainties on these meson masses are negligible. Thus,
in lattice calculations, light-quark masses are typically obtained by renormalizing the input
quark mass and tuning them to reproduce NGB masses, as described above.

3.1.1 The physical point and isospin symmetry

As mentioned in Sec. 2.1, the present review relies on the hypothesis that, at low energies, the
Lagrangian $L_{\text{QCD}} + L_{\text{QED}}$ describes nature to a high degree of precision. However, most of the
results presented below are obtained in pure QCD calculations, which do not include QED.
Quite generally, when comparing QCD calculations with experiment, radiative corrections
need to be applied. In pure QCD simulations, where the parameters are fixed in terms of
the masses of some of the hadrons, the electromagnetic contributions to these masses must
be discussed. How the matching is done is generally ambiguous because it relies on the
unphysical separation of QCD and QED contributions. In this section, and in the following,
we discuss this issue in detail. Of course, once QED is included in lattice calculations, the
subtraction of electromagnetic contributions is no longer necessary.

Let us start from the unambiguous case of QCD+QED. As explained in the introduction
of this section, the physical quark masses are the parameters of the Lagrangian such that a
given set of experimentally measured, dimensionful hadronic quantities are reproduced by the
theory. Many choices are possible for these quantities, but in practice many lattice groups use pseudoscalar meson masses, as they are easily and precisely obtained both by experiment, and through lattice simulations. For example, in the four-flavour case, one can solve the system

\begin{align}
M_{\pi^+}(m_u, m_d, m_s, m_c, \alpha) &= M_{\pi^+}^{\text{exp}}, \\
M_{K^+}(m_u, m_d, m_s, m_c, \alpha) &= M_{K^+}^{\text{exp}}, \\
M_{K^0}(m_u, m_d, m_s, m_c, \alpha) &= M_{K^0}^{\text{exp}}, \\
M_{D^0}(m_u, m_d, m_s, m_c, \alpha) &= M_{D^0}^{\text{exp}},
\end{align}

where we assumed that

- all the equations are in the continuum and infinite-volume limits;
- the overall scale has been set to its physical value, generally through some lattice-scale setting procedure involving a fifth dimensionful input;
- the quark masses \( m_q \) are assumed to be renormalized from the bare, lattice ones in some given continuum renormalization scheme;
- \( \alpha = \frac{e^2}{4\pi} \) is the fine-structure constant expressed as function of the positron charge \( e \), generally set to the Thomson limit \( \alpha = 0.007297352 \ldots \) \[7\];
- the mass \( M_h(m_u, m_d, m_s, m_c, \alpha) \) of the meson \( h \) is a function of the quark masses and \( \alpha \). The functional dependence is generally obtained by choosing an appropriate parameterization and performing a global fit to the lattice data;
- the superscript \( \text{exp.} \) indicates that the mass is an experimental input, lattice groups use in general the values in the Particle Data Group review \[7\].

However, ambiguities arise with simulations of QCD only. In that case, there is no experimentally measurable quantity that emerges from the strong interaction only. The missing QED contribution is tightly related to isospin-symmetry breaking effects. Isospin symmetry is explicitly broken by the differences between the up- and down-quark masses \( \delta m = m_u - m_d \), and electric charges \( \delta Q = Q_u - Q_d \). Both these effects are, respectively, of order \( \mathcal{O}(\delta m / \Lambda_{\text{QCD}}) \) and \( \mathcal{O}(\alpha) \), and are expected to be \( \mathcal{O}(1\%) \) of a typical isospin-symmetric hadronic quantity. Strong and electromagnetic isospin-breaking effects are of the same order and therefore cannot, in principle, be evaluated separately without introducing strong ambiguities. Because these effects are small, they can be treated as a perturbation:

\[ X(m_u, m_d, m_s, m_c, \alpha) = \tilde{X}(m_{ud}, m_s, m_c) + \delta m A_X(m_{ud}, m_s, m_c) + \alpha B_X(m_{ud}, m_s, m_c), \]

for a given hadronic quantity \( X \), where \( m_{ud} = \frac{1}{2}(m_u + m_d) \) is the average light-quark mass. There are several things to notice here. Firstly, the neglected higher-order \( \mathcal{O}(\delta m^2, \alpha \delta m, \alpha^2) \) corrections are expected to be \( \mathcal{O}(10^{-4}) \) relatively to \( X \), which at the moment is way beyond the relative statistical accuracy that can be delivered by a lattice calculation. Secondly, this is not strictly speaking an expansion around the isospin-symmetric point, the electromagnetic interaction has also symmetric contributions. From this last expression the previous statements about ambiguities become clearer. Indeed, the only unambiguous prediction one can perform is to solve Eqs. \( (23) \text{--}(26) \) and use the resulting parameters to obtain a prediction for \( X \), which is represented by the left-hand side of Eq. \( (27) \). This prediction will be the sum
of the QCD isospin-symmetric part $\hat{X}$, the strong isospin-breaking effects $X^{SU(2)} = \delta m A_X$, and the electromagnetic effects $X^\gamma = \alpha B_X$. Obtaining any of these terms individually requires extra, unphysical conditions to perform the separation. To be consistent with previous editions of FLAG, we also define $\hat{X} = \hat{X} + X^{SU(2)}$ to be the $\alpha \to 0$ limit of $X$.

With pure QCD simulations, one typically solves Eqs. (23)–(26) by equating the QCD, isospin-symmetric part of a hadron mass $M_h$, result of the simulations, with its experimental value $M_h^{exp}$. This will result in an $O(\delta m, \alpha)$ mis-tuning of the theory parameters which will propagate as an error on predicted quantities. Because of this, in principle, one cannot predict hadronic quantities with a relative accuracy higher than $O(1\%)$ from pure QCD simulations, independently on how the target $X$ is sensitive to isospin breaking effects. If one performs a complete lattice prediction of the physical value of $X$, it can be of phenomenological interest to define in some way $\hat{X}$, $X^{SU(2)}$, and $X^\gamma$. If we keep $m_{ud}$, $m_s$ and $m_c$ at their physical values in physical units, for a given renormalization scheme and scale, then these three quantities can be extracted by setting successively and simultaneously $\alpha$ and $\delta m$ to 0. This is where the ambiguity lies: in general the $\delta m = 0$ point will depend on the renormalization scheme used for the quark masses. In the next section, we give more details on that particular aspect and discuss the order of scheme ambiguities.

### 3.1.2 Ambiguities in the separation of isospin-breaking contributions

In this section, we discuss the ambiguities that arise in the individual determination of the QED contribution $X^\gamma$ and the strong-isospin correction $X^{SU(2)}$ defined in the previous section. Throughout this section, we assume that the isospin-symmetric quark masses $m_{ud}$, $m_s$ and $m_c$ are always kept fixed in physical units to the values they take at the QCD+QED physical point in some given renormalization scheme. Let us assume that both up and down masses have been renormalized in an identical mass-independent scheme which depends on some energy scale $\mu$. We also assume that the renormalization procedure respects chiral symmetry so that quark masses renormalize multiplicatively. The renormalization constants of the quark masses are identical for $\alpha = 0$ and therefore the renormalized mass of a quark has the general form

$$m_q(\mu) = Z_m(\mu)[1 + \alpha Q_{tot}^2 \delta Z^{(0)}(\mu) + \alpha Q_{tot} Q_m \delta Z^{(1)}(\mu) + \alpha Q_q^2 \delta Z^{(2)}(\mu)]m_q(0),$$

(28)

up to $O(\alpha^2)$ corrections, where $m_q(0)$ is the bare quark mass, and where $Q_{tot}$ and $Q_q$ are the sum of all quark charges and squared charges, respectively. Throughout this section, a subscript $ud$ generally denotes the average between up and down quantities and $\delta$ the difference between the up and the down quantities. The source of the ambiguities described in the previous section is the mixing of the isospin-symmetric mass $m_{ud}$ and the difference $\delta m$ through renormalization. Using Eq. (28) one can make this mixing explicit at leading order in $\alpha$:

$$\left(\begin{array}{c} m_{ud}(\mu) \\ \delta m(\mu) \end{array}\right) = Z_m(\mu)[1 + \alpha Q_{tot}^2 \delta Z^{(0)}(\mu) + \alpha M^{(1)}(\mu) + \alpha M^{(2)}(\mu)] \left(\begin{array}{c} m_{ud}(0) \\ \delta m(0) \end{array}\right),$$

(29)

with the mixing matrices

$$M^{(1)}(\mu) = \delta Z^{(1)}(\mu) Q_{tot} \left(\begin{array}{c} Q_{ud} \\ \delta Q \end{array}\right), \quad \text{and} \quad M^{(2)}(\mu) = \delta Z^{(2)}(\mu) \left(\begin{array}{c} Q_{ud}^2 \\ 4 Q_{ud}^2 \delta Q \end{array}\right).$$

(30)

Now let us assume that for the purpose of determining the different components in Eq. (27), one starts by tuning the bare masses to obtain equal up and down masses, for some small
coupling $\alpha_0$ at some scale $\mu_0$, i.e., $\delta m(\mu_0) = 0$. At this specific point, one can extract the pure QCD, and the QED corrections to a given quantity $X$ by studying the slope of $\alpha$ in Eq. (27). From these quantities the strong isospin contribution can then readily be extracted using a nonzero value of $\delta m(\mu_0)$. However, if now the procedure is repeated at another coupling $\alpha$ and scale $\mu$ with the same bare masses, it appears from Eq. (29) that $\delta m(\mu) \neq 0$. More explicitly,

$$\delta m(\mu) = m_{ud}(\mu_0) \frac{Z_m(\mu)}{Z_m(\mu_0)} [\alpha \Delta_Z(\mu) - \alpha_0 \Delta_Z(\mu_0)],$$

where

$$\Delta_Z(\mu) = Q_{\text{tot}} \delta Q \delta Z^{(1)}(\mu) + \delta Q^2 \delta Z^{(2)}(\mu),$$

up to higher-order corrections in $\alpha$ and $\alpha_0$. In other words, the definitions of $\bar{X}$, $X^{SU(2)}$, and $X^\gamma$ depend on the renormalization scale at which the separation was made. This dependence, of course, has to cancel in the physical sum $X$. One can notice that at no point did we mention the renormalization of $\alpha$ itself, which, in principle, introduces similar ambiguities. However, the corrections coming from the running of $\alpha$ are $O(\alpha^2)$ relatively to $X$, which, as justified above, can be safely neglected. Finally, important information is provided by Eq. (31): the scale ambiguities are $O(\alpha m_{ud})$. For physical quark masses, one generally has $m_{ud} \simeq \delta m$. So by using this approximation in the first-order expansion Eq. (27), it is actually possible to define unambiguously the components of $X$ up to second-order isospin-breaking corrections. Therefore, in the rest of this review, we will not keep track of the ambiguities in determining pure QCD or QED quantities. However, in the context of lattice simulations, it is crucial to notice that $m_{ud} \simeq \delta m$ is only accurate at the physical point. In simulations at larger-than-physical pion masses, scheme ambiguities in the separation of QCD and QED contributions are generally large. Once more, the argument made here assumes that the isospin-symmetric quark masses $m_{ud}$, $m_s$, and $m_c$ are kept fixed to their physical value in a given scheme while varying $\alpha$. Outside of this assumption there is an additional isospin-symmetric $O(\alpha m_q)$ ambiguity between $\bar{X}$ and $X^\gamma$.

Such separation on lattice-QCD+QED simulation results appeared for the first time in RBC 07 [8] and Blum 10 [9], where the scheme was implicitly defined around the $\chi PT$ expansion. In that setup, the $\delta m(\mu_0) = 0$ point is defined in pure QCD, i.e., $\alpha_0 = 0$ in the previous discussion. The QCD part of the kaon-mass splitting from the first FLAG review [10] is used as an input in RM123 11 [11], which focuses on QCD isospin corrections only. It therefore inherits from the convention that was chosen there, which is also to set $\delta m(\mu_0) = 0$ at zero QED coupling. The same convention was used in the follow-up works RM123 13 [12] and RM123 17 [13]. The BMW collaboration was the first to introduce a purely hadronic scheme in its electro-quenched study of the baryon octet mass splittings [14]. In this work, the quark mass difference $\delta m(\mu)$ is swapped with the mass splitting $\Delta M^2$ between the connected $\bar{u}u$ and $\bar{d}d$ pseudoscalar masses. Although unphysical, this quantity is proportional [15] to $\delta m(\mu)$ and $O(\alpha m_{ud})$ chiral corrections. In this scheme, the quark masses are assumed to be equal at $\Delta M^2 = 0$, and the $O(\alpha m_{ud})$ corrections to this statement are analogous to the scale ambiguities mentioned previously. The same scheme was used with the same data set for the determination of light-quark masses BMW 16 [16]. The BMW collaboration used a different hadronic scheme for its determination of the nucleon-mass splitting BMW 14 [17] using full QCD+QED simulations. In this work, the $\delta m = 0$ point was fixed by imposing the baryon splitting $M_{\Sigma^0} - M_{\Sigma^-}$ to cancel. This scheme is quite different from the other ones presented here, in the sense that its intrinsic ambiguity is not $O(\alpha m_{ud})$. What motivates
this choice here is that $M_{\Sigma^+} - M_{\Sigma^-} = 0$ in the limit where these baryons are point particles, so the scheme ambiguity is suppressed by the compositeness of the $\Sigma$ baryons. This may sounds like a more difficult ambiguity to quantify, but this scheme has the advantage of being defined purely by measurable quantities. Moreover, it has been demonstrated numerically in BMW 14\cite{17} that, within the uncertainties of this study, the $M_{\Sigma^+} - M_{\Sigma^-} = 0$ scheme is equivalent to the $\Delta M^2 = 0$ one, explicitly $M_{\Sigma^+} - M_{\Sigma^-} = -0.18(12)(6)$ MeV at $\Delta M^2 = 0$. The calculation QCDSF/UKQCD 15\cite{18} uses a “Dashen scheme,” where quark masses are tuned such that flavour-diagonal mesons have equal masses in QCD and QCD+QED. Although not explicitly mentioned by the authors of the paper, this scheme is simply a reformulation of the $\Delta M^2 = 0$ scheme mentioned previously. Finally, the recent preprint MILC 18\cite{19} also used the $\Delta M^2 = 0$ scheme and noticed its connection to the “Dashen scheme” from QCDSF/UKQCD 15.

In the previous edition of this review, the contributions $X$, $X^{SU(2)}$, and $X^\gamma$ were given for pion and kaon masses based on phenomenological information. Considerable progress has been achieved by the lattice community to include isospin-breaking effects in calculations, and it is now possible to determine these quantities precisely directly from a lattice calculation. However, these quantities generally appear as intermediate products of a lattice analysis, and are rarely directly communicated in publications. These quantities, although unphysical, have a phenomenological interest, and we encourage the authors of future calculations to quote them explicitly.

### 3.1.3 Inclusion of electromagnetic effects in lattice-QCD simulations

Electromagnetism on a lattice can be formulated using a naive discretization of the Maxwell action $S[A_\mu] = \frac{1}{4} \int d^4x \sum_{\mu,\nu} \left[ \partial_\mu A_\nu (x) - \partial_\nu A_\mu (x) \right]^2$. Even in its noncompact form, the action remains gauge-invariant. This is not the case for non-Abelian theories for which one uses the traditional compact Wilson gauge action (or an improved version of it). Compact actions for QED feature spurious photon-photon interactions which vanish only in the continuum limit. This is one of the main reason why the noncompact action is the most popular so far. It was used in all the calculations presented in this review. Gauge-fixing is necessary for noncompact actions. It was shown\cite{20,21} that gauge fixing is not necessary with compact actions, including in the construction of interpolating operators for charged states.

Although discretization is straightforward, simulating QED in a finite volume is more challenging. Indeed, the long range nature of the interaction suggests that important finite-size effects have to be expected. In the case of periodic boundary conditions, the situation is even more critical: a naive implementation of the theory features an isolated zero-mode singularity in the photon propagator. It was first proposed in\cite{22} to fix the global zero-mode of the photon field $A_\mu (x)$ in order to remove it from the dynamics. This modified theory is generally named QED$_{TL}$. Although this procedure regularizes the theory and has the right classical infinite-volume limit, it is nonlocal because of the zero-mode fixing. As first discussed in\cite{17}, the nonlocality in time of QED$_{TL}$ prevents the existence of a transfer matrix, and therefore a quantum-mechanical interpretation of the theory. Another prescription named QED$_L$, proposed in\cite{23}, is to remove the zero-mode of $A_\mu (x)$ independently for each time slice. This theory, although still nonlocal in space, is local in time and has a well-defined transfer matrix. Whether these nonlocalities constitute an issue to extract infinite-volume physics from lattice-QCD+QED$_L$ simulations is, at the time of this review, still an open question. However, it is known through analytical calculations of electromagnetic finite-size effects at
$O(\alpha)$ in hadron masses [12, 17, 23–27], meson leptonic decays [26], and the hadronic vacuum polarization [28] that QED_L does not suffer from a problematic (e.g., UV divergent) coupling of short and long-distance physics due to its nonlocality. Another strategy, first proposed in [29] and used by the QCDSF collaboration, is to bound the zero-mode fluctuations to a finite range. Although more minimal, it is still a nonlocal modification of the theory and so far finite-size effects for this scheme have not been investigated. More recently, two proposals for local formulations of finite-volume QED emerged. The first one described in [30] proposes to use massive photons to regulate zero-mode singularities, at the price of (softly) breaking gauge invariance. The second one presented in [21] avoids the zero-mode issue by using anti-periodic boundary conditions for $A_\mu(x)$. In this approach, gauge invariance requires the fermion field to undergo a charge conjugation transformation over a period, breaking electric charge conservation. These local approaches have the potential to constitute cleaner approaches to finite-volume QED. All the calculations presented in this review used QED_L or QED_TLS, with the exception of QCDSF.

Once a finite-volume theory for QED is specified, there are various ways to compute QED effects themselves on a given hadronic quantity. The most direct approach, first used in [22], is to include QED directly in the lattice simulations and assemble correlation functions from charged quark propagators. Another approach proposed in [12], is to exploit the perturbative nature of QED, and compute the leading-order corrections directly in pure QCD as matrix elements of the electromagnetic current. Both approaches have their advantages and disadvantages and as shown in [13], are not mutually exclusive. A critical comparative study can be found in [31].

Finally, most of the calculations presented here made the choice of computing electromagnetic corrections in the electro-quenched approximation. In this limit, one assumes that only valence quarks are charged, which is equivalent to neglecting QED corrections to the fermionic determinant. This approximation reduces dramatically the cost of lattice-QCD+QED calculations since it allows the reuse of previously generated QCD configurations. It also avoids computing disconnected contributions coming from the electromagnetic current in the vacuum, which are generally challenging to determine precisely. The electromagnetic contributions from sea quarks are known to be flavour-$SU(3)$ and large-$N_c$ suppressed, thus electro-quenched simulations are expected to have an $O(10\%)$ accuracy for the leading electromagnetic effects. This suppression is in principle rather weak and results obtained from electro-quenched simulations might feature uncontrolled systematic errors. For this reason, the use of the electro-quenched approximation constitutes the difference between ⋄ and ⋄ in the FLAG criterion for the inclusion of isospin breaking effects.

### 3.1.4 Lattice determination of $m_s$ and $m_{ud}$

We now turn to a review of the lattice calculations of the light-quark masses and begin with $m_s$, the isospin-averaged up- and down-quark mass $m_{ud}$, and their ratio. Most groups quote only $m_{ud}$, not the individual up- and down-quark masses. We then discuss the ratio $m_u/m_d$ and the individual determinations of $m_u$ and $m_d$.

Quark masses have been calculated on the lattice since the mid-nineties. However, early calculations were performed in the quenched approximation, leading to unquantifiable systematics. Thus, in the following, we only review modern, unquenched calculations, which include the effects of light sea quarks.

Tables 4 and 5 list the results of $N_f = 2 + 1$ and $N_f = 2 + 1 + 1$ lattice calculations of $m_s$.
and $m_{ud}$. These results are given in the $\overline{\text{MS}}$ scheme at 2 GeV, which is standard nowadays, though some groups are starting to quote results at higher scales (e.g., Ref. [32]). The tables also show the colour coding of the calculations leading to these results. As indicated earlier in this review, we treat calculations with different numbers, $N_f$, of dynamical quarks separately.

$N_f = 2 + 1$ lattice calculations

We turn now to $N_f = 2 + 1$ calculations. These and the corresponding results for $m_{ud}$ and $m_s$ are summarized in Tab. 4. Given the very high precision of a number of the results, with total errors on the order of 1%, it is important to consider the effects neglected in these calculations. Isospin-breaking and electromagnetic effects are small on $m_{ud}$ and $m_s$, and have been approximately accounted for in the calculations that will be retained for our averages. We have already commented that the effect of the omission of the charm quark in the sea is expected to be small, below our current precision. In contrast with previous editions of the FLAG report, we do not add any additional uncertainty due to these effects in the final averages.

The only new calculation since FLAG 16 is the $m_s$ determination of Maezawa 16 [33]. This new result agrees well with other determinations. RBC/UKQCD 14 [34] significantly improves on their RBC/UKQCD 12 [32] work by adding three new domain wall fermion simulations to three used previously. Two of the new simulations are performed at essentially physical pion masses ($M_\pi \simeq 139$ MeV) on lattices of about 5.4 fm in size and with lattice spacings of 0.114 fm and 0.084 fm. It is complemented by a third simulation with $M_\pi \simeq 371$ MeV, $a \simeq 0.063$ and a rather small $L \simeq 2.0$ fm. Altogether, this gives them six simulations with six unitary ($m_{\text{sea}} = m_{\text{val}}$) $M_\pi$'s in the range of 139 to 371 MeV, and effectively three lattice spacings from 0.063 to 0.114 fm. They perform a combined global continuum and chiral fit to all of their results for the $\pi$ and $K$ masses and decay constants, the $\Omega$ baryon mass and two Wilson-flow parameters. Quark masses in these fits are renormalized and run nonperturbatively in the RI-SMOM scheme. This is done by computing the relevant renormalization constant for a reference ensemble, and determining those for other simulations relative to it by adding appropriate parameters in the global fit. This new calculation passes all of our selection criteria. Its results will replace the older RBC/UKQCD 12 results in our averages.

$N_f = 2 + 1$ MILC results for light-quark masses go back to 2004 [51, 52]. They use rooted staggered fermions. By 2009 their simulations covered an impressive range of parameter space, with lattice spacings going down to 0.045 fm, and valence-pion masses down to approximately 180 MeV [45]. The most recent MILC $N_f = 2 + 1$ results, i.e., MILC 10A [40] and MILC 09A [45], feature large statistics and 2-loop renormalization. Since these data sets subsume those of their previous calculations, these latest results are the only ones that must be kept in any world average.

The PACS-CS 12 [35] calculation represents an important extension of the collaboration’s earlier 2010 computation [39], which already probed pion masses down to $M_\pi \simeq 135$ MeV, i.e., down to the physical-mass point. This was achieved by reweighting the simulations performed in PACS-CS 08 [47] at $M_\pi \simeq 160$ MeV. If adequately controlled, this procedure eliminates the need to extrapolate to the physical-mass point and, hence, the corresponding systematic error. The new calculation now applies similar reweighting techniques to include electromagnetic and $m_u \neq m_d$ isospin-breaking effects directly at the physical pion mass. Further, as in PACS-CS 10 [39], renormalization of quark masses is implemented nonperturbatively, through the Schrödinger functional method [57]. As it stands, the main drawback of the calculation, which makes the inclusion of its results in a world average of lattice results

** The results are given in the $\overline{\text{MS}}$ scheme at 3 instead of 2 GeV. We run them down to 2 GeV using numerically integrated 4-loop running [53, 54] with $N_f = 3$ and with the values of $\alpha_s(M_Z)$, $m_c$, and $m_t$ taken from Ref. [55]. The running factor is 1.106. At three loops it is only 0.2% smaller, indicating that perturbative running uncertainties are small. We neglect them here.

* The calculation includes electromagnetic and $m_u \neq m_d$ effects through reweighting.

† The fermion action used is tree-level improved.

‡ $m_s$ is determined from $m_c$ with the MILC 09 result for $m_d/m_{ud}$. Since $m_c/m_s$ is renormalization group invariant in QC, the renormalization and running of the quark masses enter indirectly through that of $m_c$ (see below).

§ The calculation includes quenched electromagnetic effects.

‡‡ What is calculated is $m_c/m_s = 11.85(16)$. $m_s$ is then obtained by combining this result with the determination $m_c(m_c) = 1.208(9)$ GeV from Ref. [56]. Finally, $m_{ud}$ is determined from $m_s$ with the MILC 09 result for $m_s/m_{ud}$.

α The bare numbers are those of MILC 04. The masses are simply rescaled, using the ratio of the 2-loop to 1-loop renormalization factors.

a The masses are renormalized nonperturbatively at a scale of 2 GeV in a couple of $N_f = 3$ RI-SMOM schemes. A careful study of perturbative matching uncertainties has been performed by comparing results in the two schemes in the region of 2 GeV to 3 GeV [42].

b The masses are renormalized and run nonperturbatively up to a scale of 40 GeV in the $N_f = 3$ SF scheme. In this scheme, nonperturbative and NLO running for the quark masses are shown to agree well from 40 GeV all the way down to 3 GeV [39].

c The masses are renormalized and run nonperturbatively up to a scale of 4 GeV in the $N_f = 3$ RI-MOM scheme. In this scheme, nonperturbative and N³LO running for the quark masses are shown to agree from 6 GeV down to 3 GeV to better than 1% [38].

d All required running is performed nonperturbatively.
inappropriate at this stage, is that for the lightest quark mass the volume is very small, corresponding to \( LM_a \approx 2.0 \), a value for which finite-volume effects will be difficult to control. Another problem is that the calculation was performed at a single lattice spacing, forbidding a continuum extrapolation. Further, it is unclear at this point what might be the systematic errors associated with the reweighting procedure.

The BMW 10A, 10B \([37, 38]\) calculation still satisfies our stricter selection criteria. They reach the physical up- and down-quark mass by interpolation instead of by extrapolation. Moreover, their calculation was performed at five lattice spacings ranging from 0.054 to 0.116 fm, with full nonperturbative renormalization and running and in volumes of up to (6 fm)\(^3\), guaranteeing that the continuum limit, renormalization, and infinite-volume extrapolation are controlled. It does neglect, however, isospin-breaking effects, which are small on the scale of their error bars.

Finally, we come to another calculation which satisfies our selection criteria, HPQCD 10 \([41]\). It updates the staggered-fermions calculation of HPQCD 09A \([44]\). In these papers, the renormalized mass of the strange quark is obtained by combining the result of a precise calculation of the renormalized charm-quark mass, \( m_c \), with the result of a calculation of the quark-mass ratio, \( m_c/m_s \). As described in Ref. \([56]\) and in Sec. 3.2, HPQCD determines \( m_c \) by fitting Euclidean-time moments of the \( \bar{c}c \) pseudoscalar density two-point functions, obtained numerically in lattice-QCD, to fourth-order, continuum perturbative expressions. These moments are normalized and chosen so as to require no renormalization with staggered fermions. Since \( m_c/m_s \) requires no renormalization either, HPQCD’s approach displaces the problem of lattice renormalization in the computation of \( m_s \) to one of computing continuum perturbative expressions for the moments. To calculate \( m_{ud} \) HPQCD 10 \([41]\) use the MILC 09 determination of the quark-mass ratio \( m_s/m_{ud} \) \([46]\).

HPQCD 09A \([44]\) obtains \( m_c/m_s = 11.85(16) \) \([44]\) fully nonperturbatively, with a precision slightly larger than 1%. HPQCD 10’s determination of the charm-quark mass, \( m_c(m_c) = 1.268(6) \),\(^2\) is even more precise, achieving an accuracy better than 0.5%.

This discussion leaves us with six results for our final average for \( m_s \): Maezawa 16 \([33]\), MILC 09A \([45]\), BMW 10A, 10B \([37, 38]\), HPQCD 10 \([41]\) and RBC/UKQCD 14 \([34]\). Assuming that the result from HPQCD 10 is 100% correlated with that of MILC 09A, as it is based on a subset of the MILC 09A configurations, we find \( m_s = 92.03(88) \) MeV with a \( \chi^2/\text{d.of.}=1.1 \).

For the light-quark mass \( m_{ud} \), the results satisfying our criteria are RBC/UKQCD 14B, BMW 10A, 10B, HPQCD 10, and MILC 10A. For the error, we include the same 100% correlation between statistical errors for the latter two as for the strange case, resulting in \( m_{ud} = 3.364(41) \) at 2 GeV in the \( \overline{\text{MS}} \) scheme (\( \chi^2/\text{d.of.}=1.1 \)). Our final estimates for the light-quark masses are

\[
\begin{align*}
N_f = 2 + 1 : & \quad m_{ud} = 3.364(41) \text{ MeV} \quad \text{Refs. [34, 37, 38, 40, 41]}, \\
& \quad m_s = 92.03(88) \text{ MeV} \quad \text{Refs. [33, 34, 37, 38, 41, 45]}. 
\end{align*}
\]

And the RGI values

\[
\begin{align*}
N_f = 2 + 1 : & \quad M_{ud}^{\text{RGI}} = 4.682(57)m(55)_{\Lambda} \text{ MeV} = 4.682(79) \text{ MeV} \quad \text{Refs. [34, 37, 38, 40, 41]}, \\
& \quad M_s^{\text{RGI}} = 128.1(1.2)m(1.5)_{\Lambda} \text{ MeV} = 128.1(1.9) \text{ MeV} \quad \text{Refs. [33, 34, 37, 38, 41, 45]}.
\end{align*}
\]

\(^2\)To obtain this number, we have used the conversion from \( \mu = 3 \text{ GeV} \) to \( m_c \) given in Ref. \([56]\).
$N_f = 2 + 1 + 1$ lattice calculations

Since the previous FLAG review, two new results for the strange-quark mass have appeared, HPQCD 18 [58] and FNAL/MILC/TUMQCD 18 [59]. In the former quark masses are renormalized nonperturbatively in the RI-SMOM scheme. The mass of the (fictitious) $\bar{s}s$ meson is used to tune the bare strange mass. The “physical” $\bar{s}s$ mass is given in QCD from the pion and kaon masses. In addition, they use the same HISQ ensembles and valence quarks as those in HPQCD 14A, where the quark masses were computed from time moments of vector-vector correlation functions. The new results are consistent with the old, with roughly the same size error, but of course with different systematics. In particular the new results avoid the use of high-order perturbation theory in the matching between lattice and continuum schemes. It is reassuring that the two methods, applied to the same ensembles, agree well.

The $N_f = 2 + 1 + 1$ results are summarized in Tab. 5. Note that the results of Ref. [60] are reported as $m_\text{ud}(2\text{GeV};N_f = 3)$ and those of Ref. [61] as $m_{\text{ud}(s)}(2\text{GeV};N_f = 4) = 93.12(69)\text{MeV}$. The average of FNAL/MILC/TUMQCD 18, HPQCD 18, ETM 14 and HPQCD 14A is $93.44(68)\text{MeV}$ with $\chi^2/\text{dof} = 1.7$. For the light-quark average we use ETM 14A and FNAL/MILC/TUMQCD 18 with an average $3.410(43)$ and a $\chi^2/\text{dof} = 3$. We note these $\chi^2$ values are large. For the case of the light-quark masses this is mostly due to ETM 14(A) masses lying significantly above the rest, but in the case of $m_s$ there is also some tension between the recent and very precise results of HPQCD 18 and FNAL/MILC/TUMQCD 18. Also note that the 2+1-flavour values are consistent with the four-flavour ones, so in all cases we have decided to simply quote averages according to FLAG rules, including stretching factors for the errors based on $\chi^2$ values of our fits.

\begin{align}
N_f = 2 + 1 + 1 : \\
m_{\text{ud}} = 3.410(43) \text{ MeV} & \quad \text{Refs. [59, 61]}, \\
m_s = 93.44(68) \text{ MeV} & \quad \text{Refs. [58–61]}.
\end{align}

and the RGI values

\begin{align}
N_f = 2 + 1 + 1 : \\
M_{\text{ud}}^{\text{RGI}} = 4.746(60)m_{(55)}\Lambda \text{ MeV} = 4.746(82) \text{ MeV} & \quad \text{Refs. [59, 61]}, \\
M_s^{\text{RGI}} = 130.0(0.9)m_{(1.5)}\Lambda \text{ MeV} = 130.0(1.8) \text{ MeV} & \quad \text{Refs. [58–61]}.
\end{align}

In Figs. 1 and 2 the lattice results listed in Tabs. 4 and 5 and the FLAG averages obtained at each value of $N_f$ are presented and compared with various phenomenological results.

3.1.5 Lattice determinations of $m_s/m_{\text{ud}}$

The lattice results for $m_s/m_{\text{ud}}$ are summarized in Tab. 6. In the ratio $m_s/m_{\text{ud}}$, one of the sources of systematic error—the uncertainties in the renormalization factors—drops out.

$N_f = 2 + 1$ lattice calculations

For $N_f = 2 + 1$ our average has not changed since the last version of the review and is based on the result RBC/UKQCD 14B, which replaces RBC/UKQCD 12 (see Sec. 3.1.4), and on the results MILC 09A and BMW 10A, 10B. The value quoted by HPQCD 10 does not represent independent information as it relies on the result for $m_s/m_{\text{ud}}$ obtained by the MILC collaboration. Averaging these results according to the prescriptions of Sec. 2.3 gives
Bare quark masses are renormalized nonperturbatively in the RI-SMOM scheme at scales $\mu \sim 2 - 5$ GeV for different lattice spacings and translated to the $\overline{\text{MS}}$ scheme. Perturbative running is then used to run all results to a reference scale $\mu = 3$ GeV.

As explained in the text, $m_s$ is obtained by combining the results $m_c(5\text{ GeV}; N_f = 4) = 0.8905(56)$ GeV and $(m_c/m_s)(N_f = 4) = 11.652(65)$, determined on the same data set. A subsequent scale and scheme conversion, performed by the authors, leads to the value 93.6(8). In the table, we have converted this to $m_s(2\text{ GeV}; N_f = 4)$, which makes a very small change.

Table 5: $N_f = 2 + 1 + 1$ lattice results for the masses $m_{ud}$ and $m_s$.

\[
\begin{array}{ccccccc}
\text{Collaboration} & \text{Ref.} & \text{Publication status} & \text{Chiral extrapolation} & \text{Continuum extrapolation} & \text{Finite volume} & \text{Renormalization} & m_{ud} & m_s \\
\hline
\text{HPQCD 18}^\dagger & [58] & A & \bigstar & \bigstar & \bigstar & \bigstar & \bullet & 94.49(96) \\
\text{FNAL/MILC/TUMQCD 18} & [59] & A & \bigstar & \bigstar & \bigstar & \bigstar & \bullet & 92.52(40)(56) \\
\text{HPQCD 14A}^\ddagger & [60] & A & \bigstar & \bigstar & \bigstar & \bigstar & \bullet & 93.7(8) \\
\text{ETM 14}^\ddagger & [61] & A & \bigcirc & \bigstar & \bigstar & \bigstar & \bullet & 99.6(3.6)(2.3) \\
\end{array}
\]

> $m_s/m_{ud} = 27.42(12)$ with $\chi^2/\text{dof} \simeq 0.2$. Since the errors associated with renormalization drop out in the ratio, the uncertainties are even smaller than in the case of the quark masses themselves: the above number for $m_s/m_{ud}$ amounts to an accuracy of 0.5%.

At this level of precision, the uncertainties in the electromagnetic and strong isospin-breaking corrections might not be completely negligible. Nevertheless, we decide not to add any uncertainty associated with this effect. The main reason is that most recent determinations try to estimate this uncertainty themselves and found an effect smaller than naive power counting estimates (see $N_f = 2 + 1 + 1$ section).

\[N_f = 2 + 1 : \quad m_s/m_{ud} = 27.42 (12) \quad \text{Refs.} \ [34, 37, 38, 45]. \quad (37)\]

$N_f = 2 + 1 + 1$ lattice calculations

For $N_f = 2 + 1 + 1$ there are three results, MILC 17 [68], ETM 14 [61] and FNAL/MILC 14A [69], all of which satisfy our selection criteria.

MILC 17 uses 24 HISQ staggered-fermion ensembles at six values of the lattice spacing in the range $0.15 \text{ fm–0.03 fm}$.

ETM 14 uses 15 twisted mass gauge ensembles at three lattice spacings ranging from 0.062 to 0.089 fm (using $f_\pi$ as input), in boxes of size ranging from 2.0 to 3.0 fm, and pion masses from 210 to 440 MeV (explaining the tag $\bigcirc$ in the chiral extrapolation and the tag $\bigstar$ for the continuum extrapolation). The value of $M_\pi L$ at their smallest pion mass is 3.2 with more than two volumes (explaining the tag $\bigcirc$ in the finite-volume effects). They fix the strange mass with the kaon mass.

FNAL/MILC 14A employs HISQ staggered fermions. Their result is based on 21 ensembles at four values of the coupling $\beta$ corresponding to lattice spacings in the range from 0.057 to 0.153 fm, in boxes of sizes up to 5.8 fm, and with taste-Goldstone pion masses down to
Figure 1: $\overline{\text{MS}}$ mass of the strange quark (at 2 GeV scale) in MeV. The upper two panels show the lattice results listed in Tabs. 4 and 5, while the bottom panel collects sum rule results [62–66], and also indicates the current PDG estimate [55]. Diamonds and squares represent results based on perturbative and nonperturbative renormalization, respectively. The black squares and the grey bands represent our estimates (33) and (35). The significance of the colours is explained in Sec. 2.

130 MeV, and RMS pion masses down to 143 MeV. They fix the strange mass with $M_{ss}$, corrected for electromagnetic effects with $\epsilon = 0.84(20)$ [70]. All of our selection criteria are satisfied with the tag $\star$. Thus our average is given by $m_s/m_{ud} = 27.23 \pm 10$, where the error includes a large stretching factor equal to $\sqrt{x^2/dof} \approx 1.6$, coming from our rules for the averages discussed in Sec. 2.2. As mentioned already this is mainly due to ETM 14(A) values lying significantly above the averages for the individual masses.

$$N_f = 2 + 1 + 1 : \quad m_s/m_{ud} = 27.23 \pm 10 \quad \text{Refs. [61, 68, 69]},$$

which corresponds to an overall uncertainty equal to 0.4%. It is worth noting that [68] estimates the EM effects in this quantity to be $\sim 0.18\%$.

All the lattice results listed in Tab. 6 as well as the FLAG averages for each value of $N_f$ are reported in Fig. 3 and compared with $\chi$PT, sum rules and the updated PDG estimate $m_s/m_{ud} = 27.5(3)$ [55].
Figure 2: Mean mass of the two lightest quarks, \( m_{ud} = \frac{1}{2}(m_u + m_d) \). The bottom panel shows the PDG result and results based on sum rules [62, 65, 67] (for more details see Fig. 1).

### 3.1.6 Lattice determination of \( m_u \) and \( m_d \)

In addition to reviewing computations of individual \( m_u \) and \( m_d \) quark masses, we will also determine FLAG averages for the parameter \( \epsilon \) related to the violations of Dashen’s theorem

\[
\epsilon = \frac{(\Delta M_K^2 - \Delta M_\pi^2)^\gamma}{\Delta M_\pi^2},
\]

where \( \Delta M_\pi^2 = M_{\pi^+}^2 - M_{\pi^0}^2 \) and \( \Delta M_K^2 = M_{K^+}^2 - M_{K^0}^2 \) are the pion and kaon squared mass splittings, respectively. The superscript \( \gamma \), here and in the following, denotes corrections that arise from electromagnetic effects only. This parameter is often a crucial intermediate quantity in the extraction of the individual light-quark masses. Indeed, it can be shown using the \( G \)-parity symmetry of the pion triplet that \( \Delta M_\pi^2 \) does not receive \( O(\delta m) \) isospin-breaking corrections. In other words

\[
\Delta M_\pi^2 = (\Delta M_\pi^2)^\gamma \quad \text{and} \quad \epsilon = \frac{(\Delta M_K^2)^\gamma}{\Delta M_\pi^2} - 1,
\]

1 The calculation includes electromagnetic effects.

0 The errors are statistical, chiral and finite volume.

* The calculation includes electromagnetic and $m_{u} \neq m_{d}$ effects through reweighting.

+ The fermion action used is tree-level improved.

† The calculation includes quenched electromagnetic effects.

Table 6: Lattice results for the ratio $m_s/m_{ud}$.

at leading-order in the isospin-breaking expansion. The difference $(\Delta M_{\pi}^2)^{SU(2)}$ was estimated in previous editions of FLAG through the $\epsilon_m$ parameter. However, consistent with our leading-order truncation of the isospin-breaking expansion, it is simpler to ignore this term. Once known, $\epsilon$ allows one to consistently subtract the electromagnetic part of the kaon splitting to obtain the QCD splitting $(\Delta M_{K}^2)^{SU(2)}$. In contrast with the pion, the kaon QCD splitting is sensitive to $\delta m$, and, in particular, proportional to it at leading order in $\chi$PT. Therefore, the knowledge of $\epsilon$ allows for the determination of $\delta m$ from a chiral fit to lattice-QCD data. Originally introduced in another form in [75], $\epsilon$ vanishes in the $SU(3)$ chiral limit, a result known as Dashen’s theorem. However, in the 1990’s numerous phenomenological papers pointed out that $\epsilon$ might be an $O(1)$ number, indicating a significant failure of $SU(3)$ $\chi$PT in the description of electromagnetic effects on light meson masses. However, the phenomenological determinations of $\epsilon$ feature some level of controversy, leading to the rather imprecise estimate $\epsilon = 0.7(5)$ given in the first edition of FLAG. In this edition of the review, we quote below more precise averages for $\epsilon$, directly obtained from lattice-QCD+QED simulations. We refer

Figure 3: Results for the ratio $m_s/m_{ud}$. The upper part indicates the lattice results listed in Tab. 6 together with the FLAG averages for each value of $N_f$. The lower part shows results obtained from $\chi$PT and sum rules [65, 71–74], together with the current PDG estimate [55].
In the $N_f = 2+1+1$ sector, MILC 18 [19] computed $\epsilon$ using $N_f = 2+1$ asqtad electro-quenched QCD+QED$_{TL}$ simulations and extracted the ratio $m_u/m_d$ from a new set of $N_f = 2+1+1$ HISQ QCD simulations. Although $\epsilon$ comes from $N_f = 2+1$ simulations, $(\Delta M_K^2)^{SU(2)}$, which is about three times larger than $(\Delta M_K^2)^{\gamma}$, has been determined in the $N_f = 2+1+1$ theory. We therefore chose to classify this result as a four-flavour one. This result is explicitly described by the authors as an update of MILC 17 [68]. In MILC 17 [68], $m_u/m_d$ is determined as a side-product of a global analysis of heavy-meson decay constants, using a preliminary version of $\epsilon$ from MILC 18 [19]. In FNAL/MILC/TUMQCD 18 [59] the ratio $m_u/m_d$ from MILC 17 [68] is used to determine the individual masses $m_u$ and $m_d$ from a new calculation of $m_{ud}$. The work RM123 17 [13] is the continuation the $N_f = 2$ result named RM123 13 [12] in the previous edition of FLAG. This group now uses $N_f = 2+1+1$ ensembles from ETM 10 [77], however still with a rather large minimum pion mass of 270 MeV, leading to the $\circ$ rating for chiral extrapolations. In the $N_f = 2+1$ sector, BMW 16 [16] reuses the data set produced from their determination of the light baryon octet mass splittings [14] using electro-quenched QCD+QED$_{TL}$ smeared clover fermion simulations. Finally, MILC 16 [78], which is a preliminary result for the value of $\epsilon$ published in MILC 18 [19], also provides a $N_f = 2+1$ computation of the ratio $m_u/m_d$.

MILC 09A [45] uses the mass difference between $K^0$ and $K^+$, from which they subtract electromagnetic effects using Dashen’s theorem with corrections, as discussed in the introduction of this section. The up and down sea quarks remain degenerate in their calculation, fixed to the value of $m_{ud}$ obtained from $M_{\bar{s}0}$. To determine $m_u/m_d$, BMW 10A, 10B [37, 38] follow a slightly different strategy. They obtain this ratio from their result for $m_u/m_{ud}$ combined with a phenomenological determination of the isospin-breaking quark-mass ratio $Q = 22.3(8)$, from $\eta \to 3\pi$ decays [79] (the decay $\eta \to 3\pi$ is very sensitive to QCD isospin breaking but fairly insensitive to QED isospin breaking). Instead of subtracting electromagnetic effects using phenomenology, RBC 07 [8] and Blum 10 [9] actually include a quenched electromagnetic field in their calculation. This means that their results include corrections to Dashen’s theorem, albeit only in the presence of quenched electromagnetism. Since the up and down quarks in the sea are treated as degenerate, very small isospin corrections are neglected, as in MILC’s calculation. PACS-CS 12 [35] takes the inclusion of isospin-breaking effects one step further. Using reweighting techniques, it also includes electromagnetic and $m_u - m_d$ effects in the sea. However, they do not correct for the large finite-volume effects coming from electromagnetism in their $M_\pi L \sim 2$ simulations, but provide rough estimates for their size, based on Ref. [23]. QCDSF/UKQCD 15 [80] uses QCD+QED dynamical simulations performed at the $SU(3)$-flavour-symmetric point, but at a single lattice spacing, so they do not enter our average. The smallest partially quenched ($m_{sea} \neq m_{val}$) pion mass is greater than 200 MeV, so our chiral-extrapolation criteria require a $\circ$ rating. Concerning finite-volume effects, this work uses three spatial extents $L$ of 1.6 fm, 2.2 fm, and 3.3 fm. QCDSF/UKQCD 15 claims that the volume dependence is not visible on the two largest volumes, leading them to assume that finite-size effects are under control. As a consequence of that, the final result for quark masses does not feature a finite-volume extrapolation or an estimation of the finite-volume uncertainty. However, in their work on the QED corrections to the hadron spectrum [80] based on the same ensembles, a volume study shows some level of compatibility with the QED$_{TL}$ finite-volume effects derived in [24]. We see two issues here. Firstly, the analytical result quoted from [24] predicts large, $O(10\%)$ finite-size effects from QED on the meson masses at the values of $M_\pi L$ considered in QCDSF/UKQCD 15, which is inconsistent with the statement made in the paper. Secondly, it is not known that the zero-mode regularization

\(^\dagger\) MILC 17 additionally quotes an optional 0.0032 uncertainty on \(m_u/m_d\) corresponding to QED and QCD separation scheme ambiguities. Because this variation is not per se an error on the determination of \(m_u/m_d\) and because it is generally not included in other results, we choose to omit it here. This result critically depends on \(\epsilon\) determined in MILC 18, which is unpublished at present.

\(^\dagger\) Values obtained by combining the HPQCD 10 result for \(m_s\) with the MILC 09 results for \(m_s/m_u d\) and \(m_u/m_d\).

\(^+\) The fermion action used is tree-level improved.

\(a\) The masses are renormalized and run nonperturbatively up to a scale of 100 GeV in the \(N_f = 2\) SF scheme. In this scheme, nonperturbative and NLO running for the quark masses are shown to agree well from 100 GeV all the way down to 2 GeV [81].

\(b\) The masses are renormalized and run nonperturbatively up to a scale of 4 GeV in the \(N_f = 3\) RI-MOM scheme. In this scheme, nonperturbative and N^3LO running for the quark masses are shown to agree from 6 GeV down to 3 GeV to better than 1% [38].

Table 7: Lattice results for \(m_u\), \(m_d\) (MeV) and for the ratio \(m_u/m_d\). The values refer to the \(\overline{MS}\) scheme at scale 2 GeV. The top part of the table lists the result obtained with \(N_f = 2 + 1 + 1\), while the lower part presents calculations with \(N_f = 2 + 1\).
Figure 4: Lattice results and FLAG averages at $N_f = 2 + 1$ and $2 + 1 + 1$ for the up-down quark masses ratio $m_u/m_d$, together with the current PDG estimate.

scheme used here has the same volume scaling as QED$_L$. We therefore chose to assign the ■ rating for finite volume to QCDSF/UKQCD 15. Finally, for $N_f = 2 + 1 + 1$, ETM 14\cite{61} uses simulations in pure QCD, but determines $m_u - m_d$ from the slope $\partial M_K^2/\partial m_{ud}$ and the physical value for the QCD kaon-mass splitting taken from the phenomenological estimate in FLAG 13.

Lattice results for $m_u$, $m_d$ and $m_u/m_d$ are summarized in Tab. 7. It is important to notice two major changes in the grading of these results: the introduction of an “isospin breaking” criterion and the modification of the “finite volume” criterion in the presence of QED. The colour coding is specified in detail in Sec. 2.1. Considering the important progress in the last years on including isospin-breaking effects in lattice simulations, we are now in a position where averages for $m_u$ and $m_d$ can be made without the need of phenomenological inputs. Therefore, lattice calculations of the individual quark masses using phenomenological inputs for isospin-breaking effects will be coded ■.

We start by recalling the $N_f = 2$ FLAG estimate for the light-quark masses, entirely
coming from RM123 13 [12],

\[ N_f = 2 : \]
\[ m_u = 2.40(23) \text{ MeV} \quad \text{Ref.} \ [12], \]
\[ m_d = 4.80(23) \text{ MeV} \quad \text{Ref.} \ [12], \]
\[ m_u/m_d = 0.50(4) \quad \text{Ref.} \ [12], \]

with errors of roughly 10\%, 5\% and 8\%, respectively. In these results, the errors are obtained by combining the lattice statistical and systematic errors in quadrature. For \( N_f = 2 + 1 \), the only result, which qualifies for entering the FLAG average for quark masses, is BMW 16 [16],

\[ N_f = 2 + 1 : \]
\[ m_u = 2.27(9) \text{ MeV} \quad \text{Ref.} \ [16], \]
\[ m_d = 4.67(9) \text{ MeV} \quad \text{Ref.} \ [16], \]
\[ m_u/m_d = 0.485(19) \quad \text{Ref.} \ [16], \]

with errors of roughly 4\%, 2\% and 4\%, respectively. This estimate is slightly more precise than in the previous edition of FLAG. More importantly, it now comes entirely from a lattice-QCD+QED calculation, whereas phenomenological input was used in previous editions. These numbers result in the following RGI averages

\[ N_f = 2 + 1 : \]
\[ M^\text{RGI}_u = 3.16(13)m(4)_\Lambda \text{ MeV} = 3.16(13) \text{ MeV} \quad \text{Ref.} \ [16], \]
\[ M^\text{RGI}_d = 6.50(13)m(8)_\Lambda \text{ MeV} = 6.50(15) \text{ MeV} \quad \text{Ref.} \ [16]. \] (44)

Finally, for \( N_f = 2 + 1 + 1 \), only RM123 17 [13] enters the average, giving

\[ N_f = 2 + 1 + 1 : \]
\[ m_u = 2.50(17) \text{ MeV} \quad \text{Ref.} \ [13], \]
\[ m_d = 4.88(20) \text{ MeV} \quad \text{Ref.} \ [13], \]
\[ m_u/m_d = 0.513(31) \quad \text{Ref.} \ [13]. \] (45)

with errors of roughly 7\%, 4\% and 6\%, respectively. In the previous edition of FLAG, ETM 14 [61] was used for the average. The RM123 17 result used here is slightly more precise and is free of phenomenological input. The value of \( m_u/m_d \) in MILC 17 [68] depends critically on the value of \( \epsilon \) given in MILC 18 [19], which is unpublished at present. As a consequence we choose to not include the result MILC 17 [68] in the average for the moment, despite its recent acceptance for publication. It is, however important to point out that both MILC 17 and MILC 18 results show a marginal discrepancy with RM123 17 [13] of 1.7 standard deviations. The RGI averages are

\[ N_f = 2 + 1 + 1 : \]
\[ M^\text{RGI}_u = 3.48(24)m(4)_\Lambda \text{ MeV} = 3.48(24) \text{ MeV} \quad \text{Ref.} \ [13], \]
\[ M^\text{RGI}_d = 6.80(28)m(8)_\Lambda \text{ MeV} = 6.80(29) \text{ MeV} \quad \text{Ref.} \ [13]. \] (46)

Every result for \( m_u \) and \( m_d \) used here to produce the FLAG averages relies on electro-quenched calculations, so there is some interest to comment on the size of quenching effects. Considering phenomenology and the lattice results presented here, it is reasonable for a rough estimate to use the value \((\Delta M^2_K)^\gamma \sim 2000 \text{ MeV}^2\) for the QED part of the kaon splitting. Using the arguments presented in Sec. 3.1.3, one can assume that the QED sea contribution represents \(O(10\%)\) of \((\Delta M^2_K)^\gamma\). Using \(SU(3)\) PQ\(\chi\)PT+QED [15, 82] gives a \(\sim 5\%\) effect. Keeping the more conservative 10\% estimate and using the experimental value of the kaon
splitting, one finds that the QCD kaon splitting \((\Delta M_K^2)^{SU(2)}\) suffers from a reduced 3\% quenching uncertainty. Considering that this splitting is proportional to \(m_u - m_d\) at leading order in \(SU(3)\) \(\chi PT\), we can estimate that a similar error will propagate to the quark masses. So the individual up and down masses look mildly affected by QED quenching. However, one notices that \(\sim 3\\%\) is the level of error in the new FLAG averages, and increasing significantly this accuracy will require using fully unquenched calculations.

In view of the fact that a massless up-quark would solve the strong CP-problem, many authors have considered this an attractive possibility, but the results presented above exclude this possibility: the value of \(m_u\) in Eq. (43) differs from zero by 25 standard deviations. We conclude that nature solves the strong CP-problem differently.

Finally, we conclude this section by giving the FLAG averages for \(\epsilon\) defined in Eq. (39). For \(N_f = 2 + 1 + 1\), we average the RM123 17 [13] result with the value of \((\Delta M_K^2)^{\gamma}\) from BMW 14 [17] combined with Eq. (40), giving

\[
\epsilon = 0.79(7) .
\]  

Although BMW 14 [17] focuses on hadron masses and did not extract the light-quark masses, they are the only fully unquenched QCD+QED calculation to date that qualifies to enter a FLAG average. With the exception of renormalization which is not discussed in the paper, this work has a ★ rating for every FLAG criterion considered for the \(m_u\) and \(m_d\) quark masses. For \(N_f = 2 + 1\) we use the results from BMW 16 [16]

\[
\epsilon = 0.73(17) .
\]  

These results are entirely determined from lattice-QCD+QED and represent an improvement of the error by a factor of two to three on the FLAG 16 phenomenological estimate.

It is important to notice that the \(\epsilon\) uncertainties from BMW 16 and RM123 17 are dominated by estimates of the QED quenching effects. Indeed, in contrast with the quark masses, \(\epsilon\) is expected to be rather sensitive to the sea quark-QED contributions. Using the arguments presented in Sec. 3.1.3, if one conservatively assumes that the QED sea contributions represent \(O(10\%)\) of \((\Delta M_K^2)^{\gamma}\), then Eq. (40) implies that \(\epsilon\) will have a quenching error of \(\sim 0.15\) for \((\Delta M_K^2)^{\gamma} \sim 2000\ MeV^2\), representing a large \(\sim 20\%\) relative error. It is interesting to observe that such a discrepancy does not appear between BMW 15 and RM123 17, although the \(\sim 10\%\) accuracy of both results might not be sufficient to resolve these effects. To conclude, although the controversy around the value of \(\epsilon\) has been significantly reduced by lattice-QCD+QED determinations, computing this quantity precisely requires fully unquenched simulations.

### 3.1.7 Estimates for \(R\) and \(Q\)

The quark-mass ratios

\[
R \equiv \frac{m_s - m_{ud}}{m_d - m_u} \quad \text{and} \quad Q^2 \equiv \frac{m_s^2 - m_{ud}^2}{m_d^2 - m_u^2}
\]

compare \(SU(3)\) breaking with isospin breaking. Both numbers only depend on the ratios \(m_s/m_{ud}\) and \(m_u/m_d\),

\[
R = \frac{1}{2} \left( \frac{m_s}{m_{ud}} - 1 \right) \frac{1 + \frac{m_s}{m_d}}{1 - \frac{m_u}{m_d}} \quad \text{and} \quad Q^2 = \frac{1}{2} \left( \frac{m_s}{m_{ud}} + 1 \right) R .
\]  

22
The quantity $Q$ is of particular interest because of a low-energy theorem \cite{83}, which relates it to a ratio of meson masses,

$$Q^2_M \equiv \frac{\hat{M}_K^2 - \hat{M}_\pi^2}{M_K^2 - M_\pi^2 - M_\pi^2} = \frac{1}{2}(\hat{M}_{K^+}^2 + \hat{M}_{K^0}^2), \quad \hat{M}_K^2 \equiv \frac{1}{2}(\hat{M}_{K^+}^2 + \hat{M}_{K^0}^2). \quad (51)$$

Chiral symmetry implies that the expansion of $Q^2_M$ in powers of the quark masses (i) starts with $Q^2$ and (ii) does not receive any contributions at NLO:

$$Q^\text{NLO}_M = Q. \quad (52)$$

We recall here the $N_f = 2$ estimates for $Q$ and $R$ from FLAG 16,

$$R = 40.7(3.7)(2.2), \quad Q = 24.3(1.4)(0.6), \quad (53)$$

where the second error comes from the phenomenological inputs that were used. For $N_f = 2 + 1$, we use Eqs. (37) and (43) and obtain

$$R = 38.1(1.5), \quad Q = 23.3(0.5), \quad (54)$$

where now only lattice results have been used. For $N_f = 2 + 1 + 1$ we obtain

$$R = 40.7(2.7), \quad Q = 24.0(0.8), \quad (55)$$

which are quite compatible with two- and three-flavour results. It is interesting to notice that the most recent phenomenological determination of $R$ and $Q$ from $\eta \to 3\pi$ decay \cite{84} gives the values $R = 34.4(2.1)$ and $Q = 22.1(7)$, which are marginally discrepant with the averages presented here. For $N_f = 2 + 1$, the discrepancy is 1.4 standard deviations for both $R$ and $Q$. For $N_f = 2 + 1 + 1$ it is 1.8 standard deviations. The authors of \cite{84} point out that this discrepancy is due to surprisingly large corrections to the approximation (52) used in the phenomenological analysis.

Our final results for the masses $m_u, m_d, m_{ud}, m_s$ and the mass ratios $m_u/m_d, m_s/m_{ud}, R, Q$ are collected in Tabs. 8 and 9. We separate $m_u, m_d, m_{ud}/m_d, R$ and $Q$ from $m_{ud}, m_s$ and $m_s/m_{ud}$, because the latter are completely dominated by lattice results while the former still include some phenomenological input.

### 3.2 Charm quark mass

In the following, we collect and discuss the lattice determinations of the \overline{MS} charm-quark mass $m_c$. Most of the results have been obtained by analyzing the lattice-QCD simulations of two-point heavy-light- or heavy-heavy-meson correlation functions, using as input the experimental values of the $D, D_s$, and charmonium mesons. Other groups use the moments method. The latter is based on the lattice calculation of the Euclidean time moments of pseudoscalar-pseudoscalar correlators for heavy-quark currents followed by an OPE expansion dominated by perturbative QCD effects, which provides the determination of both the heavy-quark mass and the strong-coupling constant $\alpha_s$.

The heavy-quark actions adopted by various lattice collaborations have been discussed in previous FLAG reviews \cite{5,85}, and their descriptions can be found in Sec. A.1.3. While the charm mass determined with the moments method does not need any lattice evaluation
Table 8: Our estimates for the strange-quark and the average up-down-quark masses in the \( \overline{\text{MS}} \) scheme at running scale \( \mu = 2 \text{ GeV} \). Mass values are given in MeV. In the results presented here, the error is the one which we obtain by applying the averaging procedure of Sec. 2.3 to the relevant lattice results. We have added an uncertainty to the \( N_f = 2 + 1 \) results, associated with the neglect of the charm sea-quark and isospin-breaking effects, as discussed around Eqs. (33) and (37).

of the mass-renormalization constant \( Z_m \), the extraction of \( \overline{m}_c \) from two-point heavy-meson correlators does require the nonperturbative calculation of \( Z_m \). The lattice scale at which \( Z_m \) is obtained, is usually at least of the order 2–3 GeV, and therefore it is natural in this review to provide the values of \( \overline{m}_c(\mu) \) at the renormalization scale \( \mu = 3 \text{ GeV} \). Since the choice of a renormalization scale equal to \( \overline{m}_c \) is still commonly adopted (as by PDG [55]), we have collected in Tab. 10 the lattice results for both \( \overline{m}_c(\overline{m}_c) \) and \( \overline{m}_c(3 \text{ GeV}) \), obtained for \( N_f = 2 + 1 \) and \( 2 + 1 + 1 \). This year’s review does not contain results for \( N_f = 2 \), and interested readers are referred to previous reviews [5, 85].

When not directly available in the published work, we apply a conversion factor equal either to 0.900 between the scales \( \mu = 2 \text{ GeV} \) and \( \mu = 3 \text{ GeV} \) or to 0.766 between the scales \( \mu = \overline{m}_c \) and \( \mu = 3 \text{ GeV} \), obtained using perturbative QCD evolution at four loops assuming \( \Lambda_{QCD} = 300 \text{ MeV} \) for \( N_f = 4 \).

In the next subsections, we review separately the results of \( \overline{m}_c(\overline{m}_c) \) for the various values of \( N_f \).

### 3.2.1 \( N_f = 2 + 1 \) results

The HPQCD 10 [41] result is computed from moments, using a subset of \( N_f = 2 + 1 \) Asqtad-staggered-fermion ensembles from MILC [46] and HISQ valence fermions. The charm mass is fixed from the \( \eta_c \) meson, \( M_{\eta_c} = 2.9852(34) \text{ GeV} \), corrected for \( c\bar{c} \) annihilation and electromagnetic effects. HPQCD 10 supersedes the HPQCD 08B [56] result using valence-Asqtad-staggered fermions.

\( \chi \text{QCD} \) 14 [88] uses a mixed-action approach based on overlap fermions for the valence
Table 10: Lattice results for the $\overline{\text{MS}}$-charm-quark mass $m_c(m_c)$ and $m_c(3 \, \text{GeV})$ in GeV, together with the colour coding of the calculations used to obtain these. When not directly available in a publication, we employ a conversion factor equal to 0.900 between the scales $\mu = 2 \, \text{GeV}$ and $\mu = 3 \, \text{GeV}$ (or, 0.766 between $\mu = m_c$ and $\mu = 3 \, \text{GeV}$).

quarks and domain-wall fermions for the sea quarks. They adopt six of the gauge ensembles generated by the RBC/UKQCD collaboration [42] at two values of the lattice spacing (0.087 and 0.11 fm) with unitary pion masses in the range from 290 to 420 MeV. For the valence quarks no light-quark masses are simulated. At the lightest pion mass $M_\pi \simeq 290$ MeV, $M_\pi L = 4.1$, which satisfies the tag ◦ for finite-volume effects. The strange- and charm-quark masses are fixed together with the lattice scale by using the experimental values of the $D_s$, $D^*_s$ and $J/\psi$ meson masses.

JLQCD 15B [89] determines the charm mass by using the moments method and Möbius domain-wall fermions at three values of the lattice spacing, ranging from 0.044 to 0.083 fm. They employ 15 ensembles in all, including several different pion masses and volumes. The lightest pion mass is $\simeq 230$ MeV with $M_\pi L \simeq 4.4$. The linear size of their lattices is in the range 2.6–3.8 fm.

Since FLAG 16 there have been two new results, JLQCD 16 [87] and Maezawa 16 [33]. The former supersedes JLQCD 15B as it is a published update of their previous preliminary result. The latter employs the moments method using pseudoscalar correlation functions computed with HISQ fermions on a set of 11 ensembles with lattices spacing in the range 0.04 to 0.14 fm. Only a single pion mass of 160 MeV is studied. The linear size of the lattices take on values between 2.5 and 4.5 fm.
Thus, according to our rules on the publication status, the FLAG average for the charm-quark mass at $N_f = 2 + 1$ is obtained by combining the results HPQCD 10, χQCD 14, and JLQCD 16,

$$N_f = 2 + 1: \quad \overline{m}_c(\overline{m}_c) = 1.275 \ (5) \ \text{GeV} \quad \text{Refs.} \ [41, 87, 88],$$

$$\overline{m}_c(3 \ \text{GeV}) = 0.992 \ (6) \ \text{GeV} \quad \text{Refs.} \ [41, 87, 88],$$

where the error on $\overline{m}_c(3 \ \text{GeV})$ includes a stretching factor $\sqrt{\chi^2/\text{dof}} \simeq 1.18$ as discussed in Sec. 2.2. This result corresponds to the following RGI average

$$M_{c}^{\text{RGI}} = 1.529(9)m_{(14)\Lambda} \ \text{GeV} = 1.529(17) \ \text{GeV} \quad \text{Refs.} \ [41, 87, 88].$$

### 3.2.2 $N_f = 2 + 1 + 1$ results

In FLAG 16 three results employing four dynamical quarks in the sea were discussed. ETM 14 [61] uses 15 twisted-mass gauge ensembles at three lattice spacings ranging from 0.062 to 0.089 fm, in boxes of size ranging from 2.0 to 3.0 fm and pion masses from 210 to 440 MeV (explaining the tag $\circ$ in the chiral extrapolation and the tag $\star$ for the continuum extrapolation). The value of $M_{\pi}L$ at their smallest pion mass is 3.2 with more than two volumes (explaining the tag $\circ$ in the finite-volume effects). They fix the strange mass with the kaon mass and the charm one with that of the $D_s$ and $D$ mesons.

ETM 14A [86] uses 10 out of the 15 gauge ensembles adopted in ETM 14 spanning the same range of values for the pion mass and the lattice spacing, but the latter is fixed using the nucleon mass. Two lattice volumes with size larger than 2.0 fm are employed. The physical strange and the charm mass are obtained using the masses of the $\Omega^{-}$ and $\Lambda_{c}^{+}$ baryons, respectively.

HPQCD 14A [60] employs the moments method with HISQ fermions. Their results are based on 9 out of the 21 ensembles produced by the MILC collaboration [69]. Lattice spacings range from 0.057 to 0.153 fm, with box sizes up to 5.8 fm and taste-Goldstone-pion masses down to 130 MeV. The RMS-pion masses go down to 173 MeV. The strange- and charm-quark masses are fixed using $M_{\bar{s}s} = 688.5(2.2) \ \text{MeV}$, calculated without including $\bar{s}s$ annihilation effects, and $M_{\eta_c} = 2.9863(27) \ \text{GeV}$, obtained from the experimental $\eta_c$ mass after correcting for $\bar{c}c$ annihilation and electromagnetic effects. All of the selection criteria of Sec. 2.1.1 are satisfied with the tag $\star$. \footnote{Note that in Sec. 9.7.2 different quality criteria are adopted and the HPQCD 14A paper is tagged differently for the continuum extrapolation.}

Since FLAG 16 two groups, FNAL/MILC/TUMQCD and HPQCD have produced new values for the charm-quark mass [58, 59]. The latter use nonperturbative renormalization in the RI-SMOM scheme as described in the strange quark section and the same HISQ ensembles and valence quarks as those described in HPQCD 14A [60].

The FNAL/MILC/TUMQCD groups use a new minimal-renormalon-subtraction scheme (MRS) [90] and a sophisticated, but complex, fit strategy incorporating three effective field theories: heavy quark effective theory (HQET), heavy-meson rooted all-staggered chiral perturbation theory (HMrAS\chi PT), and Symanzik effective theory for cutoff effects. Heavy-light meson masses are computed from fits to lattice-QCD correlation functions. They employ HISQ quarks on 20 MILC 2+1+1 flavour ensembles with six lattice spacings between 0.03 and 0.15 fm (the largest is used only in the estimation of the systematic error in the continuum-limit extrapolation). The pion mass is physical on several ensembles except the finest, and
\( M_f L = 3.7 \text{–} 3.9 \) on the physical mass ensembles. The light-quark masses are fixed from meson masses in pure QCD, which have been shifted from their physical values using \( O(\alpha) \) electromagnetic effects recently computed by the MILC collaboration [19], see Sec. 3.1.6 for details. The heavy-light mesons are shifted using a phenomenological formula. Using chiral perturbation theory at NLO and NNLO, the results are corrected for exponentially small finite-volume effects. They find that nonexponential finite-volume effects due to nonequilibration of topological charge are negligible compared to other quoted errors. These allow for a combined continuum, chiral, and infinite-volume limit from a global fit including 77 free parameters to 324 data points which satisfies all of the FLAG criteria.

All four results enter the FLAG average for \( N_f = 2 + 1 + 1 \) quark flavours. We note however that while the determinations of \( m_c \) by ETM 14 and 14A agree well with each other, they are incompatible with HPQCD 14A, HPQCD 18, and FNAL/MILC/TUMQCD 18 by several standard deviations. While the latter use the same configurations, the analyses are quite different and independent. As mentioned earlier, \( m_{ud} \) and \( m_s \) are also systematically high compared to their respective averages. In addition, the other four-flavour values are consistent with the three-flavour average. Combining all four results yields

\[
N_f = 2 + 1 + 1:\quad m_c(m_c) = 1.280 (13) \text{ GeV} \quad \text{Refs. [58–61, 86]},
\]

\[
m_c(3 \text{ GeV}) = 0.988 (7) \text{ GeV} \quad \text{Refs. [58–61, 86]},
\]

where the errors include large stretching factors \( \sqrt{\chi^2/\text{dof}} \approx 2.0 \) and 1.7, respectively. We have assumed 100\% correlation for statistical errors between ETM results. For HPQCD 14A, HPQCD 18, and FNAL/MILC/TUMQCD 18 we use the correlations given in Ref. [58]. Our fits have \( \chi^2/\text{dof} = 3.9 \) and 2.8, respectively. The RGI average reads as follows

\[
M_{c}^{\text{RGI}} = 1.523(11)m(14)A \text{ GeV} = 1.523(18) \text{ GeV} \quad \text{Refs. [58–61, 86]}.
\]

Figure 5 presents the results given in Tab. 10 along with the FLAG averages obtained for \( 2 + 1 \) and \( 2 + 1 + 1 \) flavours.

### 3.2.3 Lattice determinations of the ratio \( m_c/m_s \)

Because some of the results for the light-quark masses given in this review are obtained via the quark-mass ratio \( m_c/m_s \), we review these lattice calculations, which are listed in Tab. 11.

The \( N_f = 2 + 1 \) results from \( \chi \text{QCD} 14 \) and HPQCD 09A [44] are the same as described for the charm-quark mass, and in addition the latter fixes the strange mass using \( M_{ss} = 685.8(4.0) \text{ MeV} \). Since FLAG 16 another result has appeared, Maezawa 16 which does not pass our chiral-limit and finite-volume tests (as described in the previous section), though we note that it is quite consistent with the other values. Combining \( \chi \text{QCD} 14 \) and HPQCD 09A, we obtain the same result reported in FLAG 16,

\[
N_f = 2 + 1:\quad m_c/m_s = 11.82 (16) \quad \text{Refs. [44, 88]},
\]

with a \( \chi^2/\text{dof} \approx 0.85 \).

Turning to \( N_f = 2 + 1 + 1 \), in addition to the HPQCD 14A and ETM 14 calculations, already described in Sec. 3.2.2, we consider the recent FNAL/MILC/TUMQCD 18 value [59] (which updates and replaces [69]), where HISQ fermions are employed as described in the previous section. As for the HPQCD 14A result, all of our selection criteria are satisfied with
Figure 5: The charm quark mass for $2 + 1$ and $2 + 1 + 1$ flavours. For the latter a large stretching factor is used for the FLAG average due to poor $\chi^2$ from our fit.

Table 11: Lattice results for the quark-mass ratio $m_c/m_s$, together with the colour coding of the calculations used to obtain these.

the tag ★. However, some tension exists between the HPQCD and FNAL/MILC/TUMQCD results. Combining all three yields

$$N_f = 2 + 1 + 1: \quad m_c/m_s = 11.768(33) \quad \text{Refs. [59–61],}$$

(63)
where the error includes the stretching factor \( \sqrt{\chi^2/dof} \approx 1.5 \), and \( \chi^2/dof = 2.28 \). We have assumed a 100% correlation of statistical errors for FNAL/MILC/TUMQCD 18 and HPQCD 14A.

Results for \( m_c/m_s \) are shown in Fig. 6 together with the FLAG averages for \( 2 + 1 \) and \( 2 + 1 + 1 \) flavours.

![Figure 6](image.png)

Figure 6: Lattice results for the ratio \( m_c/m_s \) listed in Tab. 11 and the FLAG averages corresponding to \( 2 + 1 \) and \( 2 + 1 + 1 \) quark flavours. The latter average includes a large stretching factor on the error due a poor \( \chi^2 \) from our fit.
3.3 Bottom-quark mass

Now we review the lattice results for the $\overline{\text{MS}}$-bottom-quark mass $\overline{m}_b$. Related heavy-quark actions and observables have been discussed in the FLAG 13 and 17 reviews [5, 85], and descriptions can be found in Sec. A.1.3. In Tab. 12 we collect results for $\overline{m}_b(\overline{m}_b)$ obtained with $N_f = 2 + 1$ and $2 + 1 + 1$ quark flavours in the sea. Available results for the quark-mass ratio $m_b/m_c$ are also reported. After discussing the various results we evaluate the corresponding FLAG averages.

</table>

$^+$ The lattice spacing used in ETM 14B has been updated here.
$^\dagger$ Only two pion points are used for chiral extrapolation.
$^*$ The number that is given is $m_b(10 \text{ GeV}, N_f = 5) = 3.617(25) \text{ GeV}$.

Table 12: Lattice results for the $\overline{\text{MS}}$-bottom-quark mass $\overline{m}_b(\overline{m}_b)$ in GeV, together with the systematic error ratings for each. Available results for the quark mass ratio $m_b/m_c$ are also reported.

3.3.1 $N_f = 2 + 1$

HPQCD 13B [95] extracts $\overline{m}_b$ from a lattice determination of the $\Upsilon$ energy in NRQCD and the experimental value of the meson mass. The latter quantities yield the pole mass which is related to the $\overline{\text{MS}}$ mass in 3-loop perturbation theory. The MILC coarse (0.12 fm) and fine (0.09 fm) Asqtad-2+1-flavour ensembles are employed in the calculation. The bare light-(sea)-quark masses correspond to a single, relatively heavy, pion mass of about 300 MeV. No
estimate of the finite-volume error is given. This result is not used in our average.

The value of \( m_b(m_b) \) reported in HPQCD 10 [41] is computed in a very similar fashion to the one in HPQCD 14A described in the following section on 2+1+1 flavour results, except that MILC 2+1-flavour-Asqtad ensembles are used under HISQ valence quarks. The lattice spacings of the ensembles range from 0.18 to 0.045 fm and pion masses down to about 165 MeV. In all, 22 ensembles were fit simultaneously. An estimate of the finite-volume error based on leading-order perturbation theory for the moment ratio is also provided. Details of perturbation theory and renormalization systematics are given in Sec. 9.7.

Maezawa 16 reports a new result for the \( b \)-quark mass since the last FLAG review. However as discussed in the charm-quark section, this calculation does not satisfy the criteria to be used in the FLAG average. As in the previous review, we take the HPQCD 10 result as our average,

\[
N_f = 2 + 1 : \quad m_b(m_b) = 4.164(23) \text{ GeV} \quad \text{Ref. [41]},
\]

(64)

Since HPQCD quotes \( m_b(m_b) \) using \( N_f = 5 \) running, we used that value in the average. The corresponding 4-flavour RGI average is

\[
N_f = 2 + 1 : \quad M_b^{\text{RGI}} = 6.874(38)_{\mu}(54)_{\Lambda} \text{ GeV} = 6.874(66) \text{ GeV} \quad \text{Ref. [41]}.
\]

(65)

3.3.2 \( N_f = 2 + 1 + 1 \)

Results have been published by HPQCD using NRQCD and HISQ-quark actions (HPQCD 14B [93] and HPQCD 14A [60], respectively). In both works the \( b \)-quark mass is computed with the moments method, that is, from Euclidean-time moments of two-point, heavy-heavy-meson correlation functions (see also Sec. 9.7 for a description of the method).

In HPQCD 14B the \( b \)-quark mass is computed from ratios of the moments \( R_n \) of heavy current-current correlation functions, namely,

\[
\left[ \frac{R_n r_{n-2}}{R_{n-2} r_n} \right]^{1/2} \frac{\bar{M}_{\text{kin}}}{2m_b} = \frac{\bar{M}_{\Upsilon,\eta_b}}{2m_b(\mu)},
\]

(66)

where \( r_n \) are the perturbative moments calculated at \( N^3\text{LO} \), \( \bar{M}_{\text{kin}} \) is the spin-averaged kinetic mass of the heavy-heavy vector and pseudoscalar mesons and \( \bar{M}_{\Upsilon,\eta_b} \) is the experimental spin average of the \( \Upsilon \) and \( \eta_b \) masses. The average kinetic mass \( \bar{M}_{\text{kin}} \) is chosen since in the lattice calculation the splitting of the \( \Upsilon \) and \( \eta_b \) states is inverted. In Eq. (66), the bare mass \( m_b \) appearing on the left-hand side is tuned so that the spin-averaged mass agrees with experiment, while the mass \( \bar{m}_b \) at the fixed scale \( \mu = 4.18 \text{ GeV} \) is extrapolated to the continuum limit using three HISQ (MILC) ensembles with \( a \approx 0.15, 0.12 \text{ and } 0.09 \text{ fm} \) and two pion masses, one of which is the physical one. Their final result is \( \bar{m}_b(\mu = 4.18 \text{ GeV}) = 4.207(26) \text{ GeV} \), where the error is from adding systematic uncertainties in quadrature only (statistical errors are smaller than 0.1% and ignored). The errors arise from renormalization, perturbation theory, lattice spacing, and NRQCD systematics. The finite-volume uncertainty is not estimated, but at the lowest pion mass they have \( m_\pi L \approx 4 \), which leads to the tag \( \star \).

In HPQCD 14A the quark mass is computed using a similar strategy as above but with HISQ heavy quarks instead of NRQCD. The gauge field ensembles are the same as in HPQCD 14B above plus the one with \( a = 0.06 \text{ fm} \) (four lattice spacings in all). Since the physical \( b \)-quark mass in units of the lattice spacing is always greater than one in these calculations,
fits to correlation functions are restricted to $a m_b \leq 0.8$, and a high-degree polynomial in $a m_{\eta_b}$, the corresponding pseudoscalar mass, is used in the fits to remove the lattice-spacing errors. Finally, to obtain the physical $b$-quark mass, the moments are extrapolated to $m_{\eta_b}$. Bare heavy-quark masses are tuned to their physical values using the $\eta_b$ mesons, and ratios of ratios yield $m_b/m_c$. The $\overline{MS}$-charm-quark mass determined as described in Sec. 3.2 then gives $m_b$. The moment ratios are expanded using the OPE, and the quark masses and $\alpha_S$ are determined from fits of the lattice ratios to this expansion. The fits are complicated: HPQCD uses cubic splines for valence- and sea-mass dependence, with several knots, and many priors for 21 ratios to fit 29 data points. Taking this fit at face value results in a $\star$ rating for the continuum limit since they use four lattice spacings down to 0.06 fm. See however the detailed discussion of the continuum limit given in Sec. 9.7 on $\alpha_S$.

The third four-flavour result [92] is from the ETM collaboration and updates their preliminary result appearing in a conference proceedings [94]. The calculation is performed on a set of configurations generated with twisted-Wilson fermions with three lattice spacings in the range 0.06 to 0.09 fm and with pion masses in the range 210 to 440 MeV. The $b$-quark mass is determined from a ratio of heavy-light pseudoscalar meson masses designed to yield the quark pole mass in the static limit. The pole mass is related to the $\overline{MS}$ mass through perturbation theory at $N^3$LO. The key idea is that by taking ratios of ratios, the $b$-quark mass is accessible through fits to heavy-light (strange)-meson correlation functions computed on the lattice in the range $\sim 1–2 \times m_c$ and the static limit, the latter being exactly 1. By simulating below $m_b$, taking the continuum limit is easier. They find $m_b = 4.26(3)(10)$ GeV, where the first error is statistical and the second systematic. The dominant errors come from setting the lattice scale and fit systematics.

The next new result since FLAG 16 is from Gambino, et al. [91]. The authors use twisted-mass-fermion ensembles from the ETM collaboration and the ETM ratio method as in ETM 16. Three values of the lattice spacing are used, ranging from 0.062 to 0.089 fm. Several volumes are also used. The light-quark masses produce pions with masses from 210 to 450 MeV. The main difference with ETM 16 is that the authors use the kinetic mass defined in the heavy-quark expansion (HQE) to extract the $b$-quark mass instead of the pole mass.

The final $b$-quark mass result is FNAL/MILC/TUM 18 [59]. The mass is extracted from the same fit and analysis that is described in the charm quark mass section. Note that relativistic HISQ quarks are used (almost) all the way up to the $b$-quark mass (0.9 $a m_b$) on the finest two lattices, $a = 0.03$ and 0.042 fm. The authors investigated the effect of leaving out the heaviest points from the fit, and the result did not noticeably change.

All of the above results enter our average. We note that here the updated ETM result is consistent with the average and a stretching factor on the error is not used. The average and error is dominated by the very precise FNAL/MILC/TUM 18 value.

$$N_f = 2 + 1 + 1 : \quad \overline{m}_b(\overline{m}_b) = 4.198(12) \text{ GeV} \quad \text{Refs. [59, 60, 91–93].} \quad (67)$$

Since HPQCD quotes $\overline{m}_b(\overline{m}_b)$ using $N_f = 5$ running, we used that value in the average. We have included a 100% correlation on the statistical errors of ETM 16 and Gambino 17 since the same ensembles are used in both. This translates to the following RGI average

$$N_f = 2 + 1 + 1 : \quad M_b^{\text{RGI}} = 6.936(20)(54)_{\Lambda} \text{ GeV} = 6.936(57) \text{ GeV} \quad \text{Refs. [59, 60, 91–93].} \quad (68)$$

All the results for $\overline{m}_b(\overline{m}_b)$ discussed above are shown in Fig. 7 together with the FLAG averages corresponding to $N_f = 2 + 1$ and $2 + 1 + 1$ quark flavours.
Figure 7: The $b$-quark mass, $N_f = 2 + 1$ and $2 + 1 + 1$. The updated PDG value from Ref. [7] is reported for comparison.
